Dyeing with acid dyes requires basic end groups. Thus far, building such end groups into PETP, e.g., via amines, has not been possible without yellowing or high aminolytic degradation, resulting from the high polycondensation and spinning temperatures.

Dyeing Processes. The most important dyeing processes are the exhaust process and the continuous process; aftertreatment of PETP dyeings is very important for the quality of the dyeing.

The dyeing process most widely used with PETP fiber products is the *exhaust process.* Depending on the situation in each dye plant (wastewater) and the chemical composition of the dyed goods (presence of wool), dyeing can be carried out under pressure at HT conditions (60 – 90 min at 125 – 140 °C), or it may be carried out open or under low pressure, respectively, with carrier (60 – 90 min at 95 – 110 °C). Combining both processes is rare and used only if highly oriented PETP products are to be dyed to deep shades.

Continuous processes are also used. With the aid of saturated steam, superheated steam (pad steam process, 2 – 8 min holdup time at 160 – 180 °C), or hot air (pad thermosol process, 15 – 90 s holdup time at 180 – 220 °C), high throughputs, which improve the economics of dyeing, can be achieved. Blends of PETP with cotton and other cellulosic fibers are preferably dyed by these processes.

Aftertreatment of dyed goods is essential for the quality of the dyeing. This is especially true with regard to their fastness, but also holds for other properties of dyed goods (fibers, yarns, and textile fabrics) such as processibility, appearance, hand, and mechanical properties. In deep dyeing, particularly, residual dye remains on the fiber surface after drying and heat-setting with deleterious effects, particularly on fastness. A reducing, alkaline, postdyeing, cleaning treatment removes these dyes, as well as any oligomers that are diffused from the interior to the surface of the fibers. Temperature and pH of the postcleaning bath must be carefully controlled because of the danger of hydrolytic degradation.

2.2. Structure and Properties

2.2.1. Polymer

Chemical Structure.

Homopolymer. In addition to the OH end groups of the macromolecules, PETP fibers contain 10 – 40 milliequivalents of carboxyl (COOH) end groups per kilogram of fiber. These are produced in the melt at elevated temperature (especially beginning at 280 °C) by breaking of the ester bonds. Because COOH end groups catalyze hydrolytic degradation of the polyester, they are occasionally protected (e.g., with epoxide compounds or carbodiimides), especially in products destined for industrial use [70].

Diethylene glycol, which is present in the PETP chain in concentrations up to ca. 1 mol %, affects softening behavior of the polyester, dyeability of the fibers, and to a certain extent, lightfastness. For this reason, diglycol formation is suppressed as much as possible by adjusting the conditions of the reaction.

In addition to macromolecules, the polymer contains ca. 2 % oligomers, primarily cyclic trimers, but also linear oligomers. The former can adversely affect washing and dyeing.

Additional impurities in the polyester are acetaldehyde and degradation products. At

higher thermal loading of the melt during further processing, these can lead to formation of gel particles and discoloration.

In the solid state, PETP absorbs ca. 0.4 % of water from the atmosphere at 20 °C and 65 % relative humidity. Because even minute amounts of water can cause, or at least substantially favor, hydrolytic degradation, the polyester must be carefully dried to a moisture content below 0.01 % prior to spinning.

Copolymer. The principle of copolymerization of PETP with suitable monomers is used to improve certain fiber properties.

The relatively high glass transition temperature of the fibers limits dyeability in boiling water to light and medium shades (see Section 2.1.5). Deep shades can be obtained by using higher dyeing temperature (HT dyeing at ca. 135 °C under pressure) or carriers. When these procedures are impractical, e.g., because of the presence of wool or the contamination of wastewater, fibers of block copolymers (PETP with polyglycols) can be used [68], [69]. By loosening the noncrystalline regions, the glass transition temperature of these fibers is lowered far enough to attain both the required diffusion and the desired saturation concentration of disperse dyes in the fiber.

In differential dyeing (single bath dyeing of textile fabrics to various shades), fibers are needed that can be dyed with both cationic and disperse dyes. The sodium salt of 5-sulfoisophthalic acid [*51876-65-4*] is almost exclusively built into the PETP molecule for this purpose [69].

The low pilling property of textile fabrics, necessary for practical use, requires low-pilling PETP staple fibers (see Section 2.3.1). Low molecular mass PETP is used for these fibers. In addition, cross-links sensitive to hydrolysis are also built into the polyester with the aid of, for example, organosilicon compounds [71].

A particular requirement for home furnishings is low flammability. For years PETP fibers have been used in which flame retardants in the form of suitable phosphorus compounds are co-condensed with PETP (→ Flame Retardants) [72], [73]. In this way, flame protection becomes permanent; it cannot be lost in washing or dry cleaning.

Additives. In many cases, the polymer includes additives intended to change the normally transparent and brilliant white appearance of fiber products.

The most frequently used additive is titanium dioxide [*13463-67-7*], mostly anatase but occasionally the harder rutile, which serve to dull the fiber. Particles with average grain sizes between 0.3 and 0.4 µm are added to the transesterification product in concentrations of 0.1 – 3 %.

Dyed fiber products are made by adding soluble dyes or pigments, if extreme lightfastness of dyed goods is required, to the melt. To produce black fibers, carbon black is usually added.

Many attempts have been made to achieve permanently antistatic polyester fibers by admixture of suitable compounds. Surface resistances of 10^{10} Ω have been attained [74]. However, not much practical use has as yet been made of these possibilities. In general, the desired electrical surface conductivity is obtained by finishes applied to the fiber.

Physical – Chemical Structure. The most important structural variable of fiber-forming polymers is the *average molecular mass*. This describes the mass of the average macromolecule and is the product of the molecular mass of the monomer and the average degree of polymerization (→ Polymerization Processes). A measure of the molecular mass and, hence, the length of molecules is the specific viscosity, η_{spec}, measured in dilute solution:

$$\eta_{\mathrm{spec}} = (\eta - \eta_0)/\eta_0$$

where η is the viscosity of the solution and η_0 the viscosity of solvent. For poly(ethylene terephthalate), $\eta^{\mathrm{c}}_{\mathrm{spe}}$ is between 0.5 and 1.5, depending on the application of the fiber products.

Generally, molecular mass is described by the intrinsic viscosity [η], often designated as *IV*

$$[\eta] = \lim_{c \to 0} \eta_{\mathrm{spec}}/c$$

where c is the concentration of polymer in the solution being measured. Again, depending on the area of application, [η] for PETP ranges from 0.45 dL/g for low-pilling fibers to 1.05 dL/g for tire cord, which corresponds to a span of 50 to over 200 for the average degree of polymerization.

The *distribution of molecular mass* corresponds to that given by Flory for condensation

polymers [75]. Changes in this distribution function by degradation can be reversed by melting. The distribution function of molecular mass is rarely measured and is not used for product testing.

Melt viscosity is measured with capillary or rotary viscometers. In polymers intended for standard fibers, it is ca. 250 Pa · s at 285 °C. Melt viscosity increases rapidly with increasing $[\eta]$ and decreasing temperature. It is one of the basic variables of spinnability. The orientation of the macromolecules during filament formation, is particularly dependent on melt viscosity.

The *transition temperatures,* generally measured by differential thermal analysis, are the final determinants of the orientation, crystallization, and melting behavior of PETP. The glass transition temperature is measured as ca. 68 °C on the isotropic and amorphous polymer. It depends on the orientation and crystallinity of the polymer and thus can be as high as 100 °C in highly oriented, semicrystalline, industrial, continuous-filament yarns. In the isotropic and amorphous polymer, the crystallization temperature is ca. 100 °C; the maximum rate of crystallization is observed between 140 and 180 °C. The melting point of PETP, which depends on crystallinity and crystal size, lies between 255 and 265 °C.

Physical Structure. Poly(ethylene terephthalate) quenched from the melt is isotropic and almost amorphous. The density of amorphous PETP is 1.335 g/cm^3. The polymer can be crystallized primarily by the action of heat but also by the presence of agents such as dichloromethane or dioxane. The crystal structure is triclinic; the density of the crystalline regions is 1.515 g/cm^3 [76].

The configuration and conformation of monomeric terephthalic acid and ethylene glycol in the macromolecule are also known. Infrared spectroscopy shows that the terephthalic acid component is present in the trans configuration in the crystalline part, but in the cis configuration in the noncrystalline part. The IR method shows that the glycol component exists in the trans conformation in the undisturbed crystalline region and in both the gauche and the trans conformation in the noncrystalline region. The mass ratio of the glycol components in the gauche and trans conformations changes not only during crystallization but also during orientation and disorientation. This ratio correlates to the mechanical properties of shaped PETP articles [77].

When PETP granulate is melted and the melt is forced through spinneret holes, as-spun filaments are formed. The orientation of the macromolecules in these filaments, characterized by the birefringence Δn of the filaments, depends to a large extent on windup speed. Thus, Δn at a windup speed of 1500 m/min is only ca. 0.010, but at 3500 m/min it is as much as 0.055. Density, too, is subject to this dependence. At 1500 m/min it is ca. 1.34 g/cm^3, and at 3500 m/min it is 1.35 g/cm^3. The degrees of crystallinity behave similarly [78].

During drawing of as-spun filaments, the macromolecules are oriented further, and the birefringence of filament yarns for industrial uses increases to ca. 0.240. The ability of PETP to crystallize is exploited in many ways during drawing and also in subsequent aftertreatment. Thus, the fiber density ranges from 1.36 g/cm^3 for drawn high-shrinkage staple fibers up to 1.41 g/cm^3 for highly drawn low-shrinkage filament yarns.

2.2.2. As-Spun Yarns

Nonuniformities of as-spun yarn along a filament or filament bundle, but also from filament to filament, from bundle to bundle, or even from plant to plant, are reflected in the structure of the final product. There, they appear as differences in textile properties, primarily in dye uptake. For this reason, yarn is carefully monitored during spinning. The glass transition temperature of PETP (70 °C) causes the as-spun yarn to be quite stable at room temperature and makes measurement of orientation and even of crystallinity relatively easy. Intervening in the manufacturing process in case of deviation is then possible.

Many physical measurement techniques are available to investigate the structure of PETP as-spun yarn. The total orientation of a filament is measured by *optical birefringence.* Except for highly crystalline as-spun yarn, the birefringence is proportional to the orientation factor [44]. If suitably measured, it provides indications of any possible sheath-core structure.

Another measure of orientation is the velocity of sound and with it the *sonic modulus* [79], [80]. They change little at lower orientation and increase noticeably only at spinning speeds ≥ 2500 m/min [47].

The degree of crystallinity of as-spun yarn can be calculated easily from its *density*; care is required, however, because the densities of completely amorphous and completely crystalline PETP, required in these calculations, are not entirely independent of orientation [47]. In addition, true separation of the amorphous and crystalline phases is presumed, which is sometimes questionable.

Much information can be gained from *X-ray* investigations. Wide-angle patters or goniometry provide data on the size, quantity, and orientation of the crystallites, and the approximate degree of crystallization. With their aid, total orientation can be divided into orientation of the amorphous and of the crystalline fractions of the filament. Small angle X-ray scattering permits conclusions to be drawn concerning the superstructure, i.e., the mutual arrangement of crystalline and amorphous regions and also the state of order of the latter.

Thermal Measurements. If as-spun yarn or tow is heated at constant length beyond the softening point to ca. 100 °C, a *shrinkage stress* that corresponds to the orienting stress during spinning is created [57]. This stress is, therefore, a measure of orientation and is largely proportional to the optical birefringence. These two quantities diverge only at high spinning speeds.

If as-spun yarn is heated without restraint, it shrinks, sometimes very much. In so doing, the orienting elongation D, frozen in during spinning, is recovered; hence, D can be calculated from the *spun yarn shrinkage* [81]. As expected from theory, the quantity $D^2 - 1/D$ is approximately proportional to birefringence and shrinkage stress at constant length, which are measures of orientation [81], [82]. However, this is true only for spinning speeds up to 1500 m/min with normal quench. Beyond that, shrinkage is impeded by crystalline regions developed in the sample during spinning or by the regions created during measurement. Thus, spun yarn shrinkage goes through a maximum of 60 – 70 % at spinning speeds between 2000 and 4000 m/min and then drops rapidly with increasing speed [46], [53], [57]. In this spinning range, spun yarn shrinkage is again recommended as a measure of crystallinity, even of dyeability of the final product [53], [61].

Differential Thermal Analysis (DTA). The glass transition temperature, the temperature of the maximum rate of crystallization, the melting point of crystallites, and the final melting point can all be determined from DTA curves [47].

Mechanical Tests. If a PETP as-spun yarn is elongated at room temperature and its tensile stress is measured at the same time, the stress – strain curves shown in Figure 3 are obtained. For as-spun yarn of lower orientation, a saddle appears after the initial rise in stress, while a draw point crawls along the clamped yarn [54]. The percentage of elongation reached at the end of this saddle is called the natural draw ratio R_n of the as-spun yarn. With increasing spinning orientation, shown in the figure by higher spinning speeds, R_n decreases; this is because a greater amount of extensibility has been anticipated during spinning [57]. If spinning orientation becomes too large, R_n can no longer be specified [53], [60]. Then either the elongation of the as-spun yarn at a given load or the force necessary to produce a given elongation is used [57]. In practice, determining the operational draw ratio that imparts a definite property, such as break elongation or dye uptake to the final product might be useful. This, however, assumes that no changes occur in further processing.

Figure 3. Stress – strain curves of PETP as-spun yarns spun at four spinning speeds
Spinning speeds:
——— 1200 m/min
· · · · · · 2000 m/min
— · — · 3000 m/min
– – – – 4000 m/min

To monitor the spinning process and possibly pinpoint defects in commercial practice, tests should be limited to those that can be most read-

ily and accurately carried out and that provide averages over a sufficient quantity of as-spun yarn. Each kind of test, taken separately, is useful only for monitoring, not for control. If a test quantity exceeds the tolerance range, use of another kind of test is recommended to readjust the process conditions.

2.2.3. Drawn Materials

During drawing, PETP crystallizes in the triclinic configuration mentioned in Section 2.2.1, "Poly(ethylene terephthalate) with Very High Molecular Mass." The supermolecular structure is assumed to consist of somewhat parallel layers, inclined to the fiber axis. With increasing draw, the distance between the layers, measured in a direction normal to the layer surface, decreases, and the layers rotate more in the direction of the fiber axis [59], [83].

In practice, material that has been drawn but not processed further is almost never available as an intermediate product. A posttreatment almost always follows immediately, as described in Section 2.1.4.

2.2.4. Dyed Poly(ethylene terephthalate) Material

Fastness Properties. The lightfastness of dyed textiles for apparel and home furnishings is important in preserving their coloration. A lightfastness rating of 6 can be achieved readily in articles of unmodified PETP fibers with most commercially available disperse dyes. The lightfastness of PETP fibers, modified to be dyeable to deep shades at the boil without carrier, may be half a rating lower. Dyeings of PETP fibers, modified to be cationic dyeable, generally do not rate higher than 4 – 5 in lightfastness.

Heat-setting fastness, rubbing fastness, and washfastness of dyeings of PETP fibers meet all practical requirements. The only exception is the slightly lower washfastness of modified PETP fiber, dyeable without carrier. A wash temperature of 40 °C should not be exceeded.

Degradation and Mechanical Properties. In discussing alkaline postdyeing cleaning treatment, the danger of hydrolytic damage to PETP fibers is mentioned (see Section 2.1.5, Dyeing Processes). This damage consists of molecular degradation, which can extend to different degrees from the fiber skin to the core. The consequence, in general, is a reduction in tensile strength and breaking elongation of the fibers caused by the embrittlement connected with degradation. At the same time, the hand of the textile fabric can occasionally be changed. However, sometimes such changes of the hand are desired (e.g., by alkalization).

Another change in the properties of PETP fibers or textiles is sometimes produced by shrinkage during dyeing, which may be accompanied by crystallization processes. Carefully controlling the dimensions of, and stresses in, textile fabrics as well as the drying and setting temperatures is required.

2.3. Poly(ethylene terephthalate) Fibers

2.3.1. Staple Fibers

Special Features of the Manufacturing Process. In the manufacture of PETP staple fibers, polymers with intrinsic viscosities $[\eta]$ of 0.65 – 0.75 are generally used; for special types, polymers of much lower viscosity with $[\eta]$ ca. 0.5 are occasionally used. The equipment on which PETP staple fibers are produced is usually large, with daily production up to 50 t and more. Therefore, feeding the spinning units directly from a condensation unit makes economic sense (see also → Fibers, 3. General Production Technology) [84].

A spinning unit for PETP staple fibers consists of 8 – 32 spinning positions including their accompanying spinning shafts, aligned side by side. Each position is supplied with melt, either simultaneously or in groups, by an extruder or directly from a condensation unit [37].

Depending on the type of air quench, spinnerets may be circular with uniformly arranged spinneret holes, they may be plates in which the holes are arranged rectangularly, and finally they may be circular with an annular arrangement of holes [84]. The number of holes is based on the as-spun fineness and the feed of the spinning position. The spinneret hole shape is not always round. For profiled fibers with nonround cross sections, such as triangles, five-pointed stars, or

even hollow fibers, the holes must have profiles that exaggerate those of the final product because the profile impressed by the hole tends to blur somewhat during spinning.

The output of a spinning position has been increased from 500 g/min to 1500 g/min and more by increasing the number of spinneret holes, by forceful quenching, and by increasing the spinning speed.

For example, a filament bundle with a linear density of 8 dtex per filament is spun from an 1125-hole spinneret at a speed of 1500 m/min. The output per spinning position is 1350 g/min. A 16-position spinning machine then provides about 31 t/d of as-spun yarn in the form of a tow with total length of 2160 km and a linear density of 144 000 dtex, consisting of 18 000 individual filaments.

The length of the spinning shafts is determined by the need not only to ensure that the filaments are cooled below 70 °C but also to prevent the moving individual filaments from sticking together. The shafts are generally 5 m long but, with a suitable quench, they may be shorter [84].

Finish is applied to the filament bundle at the lower end of the shaft to ensure trouble-free packaging of the as-spun material. The spin finish is also used to impart surface characteristics to the fibers needed downstream during manufacturing and textile processing [85], [86], [87]. This is more economical and protects the environment better, but some compromises with respect to processibility during tow drawing and textile processing are unavoidable.

After the finish application, strands coming down from the spinning units are turned horizontally and combined into a tow, which is drawn off and deposited in a spinning can. Depending on the installation, these cans hold 0.5 – 2 t of tow, all of which should have the same length.

The fibrous as-spun product is preoriented; in newer spinning units with very effective quench, for example, it is characterized by a birefringence of $(8-14)\times10^{-3}$ or by a natural draw ratio of ca. 1 : 2.5.

High-speed spinning at ca. 3000 m/min, which is advantageous for textile filament yarns, has been attempted for production of PETP staple fibers [88]. Problems still exist in developing a reliable process for depositing the tow in the spinning can [89]. A sheath-core effect in the filaments also presents difficulties.

As customary in the production of staple fibers and tows from melt- or dry-spun synthetic polymers, the as-spun tows are combined and further processed continuously as a tow band. The tow band (up to ca. 1.20 m wide) is first immersed in a warm bath where the stresses in the individual strands are equalized; the tow is thoroughly wetted, and if necessary, additional finish is added. From the immersion bath, the tow enters the draw zone between two sets of rolls [85].

During drawing, the draw points or draw zones of all filaments in the band must be as close together as possible and must not wander [85]. A number of drawing processes are available for this [90]. If the tow is cold when it enters the draw zone, the yield stress must be lowered by sudden heating, e.g., via a steam jet, so that drawing can occur. In this process, the draw ratio is limited, and if necessary, a second drawing step must be provided.

If the tow is heated on hot feed rolls, drawing begins on the last or next-to-last feed roll and can even be facilitated, if necessary, by an immersion bath under the third roll from the end. It is also usual to pass the tow through an additional hot zone in the draw stand. With this process, reaching higher draws with one drawing is possible.

Drawing in water is a compromise in which only the last feed roll is heated and dipped into the hot water draw bath. Drawing begins at that point.

If postdrawing is to be accomplished in a separate draw zone, the draw rolls of the first stage are heated because they represent the feed rolls of the second draw, which is then carried out in a heating device.

The stress – strain behavior of the end product can be preselected by the draw ratio but is more critically affected by the type and place of heat-setting. Thus, fibers that are to exhibit a steep stress – strain curve with high initial modulus, similar to cotton, are relatively highly drawn, e.g., 1 : 4.5 to 1 : 6, depending on the as-spun yarn. After drawing, the tow is heat-set under tension, usually at constant length. The heat-setting temperature is between 160 and 230 °C, depending on the shrinkage desired. After setting, the tow traverses a cooling zone under

tension and then enters the crimper. To facilitate crimping, it is first slightly moistened or steamed. The tow must not become too hot in the crimper; otherwise it relaxes and textile properties deteriorate. After crimping, finish can again be applied if necessary, in which case the tow must again be carefully dried [90].

Fibers that are to have a flat stress – strain curve similar to wool do not need to be so highly drawn; a draw ratio range of ca. 1 : 2.5 to 1 : 3 will suffice. After drawing, the tow is sent immediately to the crimper via a short steam zone. The crimp is then heat-set without tension, often on traveling grate machines. The heat-setting temperature, ca. 120 – 180 °C, is selected according to the amount of shrinkage desired in the end product. The flat stress – strain curve is formed by the tensionless setting, and the crimp becomes highly stable.

Finally, the crimped and, if necessary, shrinkage-stabilized tow is packaged. Either it is compressed into a bale and sold as endless tow, or it passes through a cutter and is cut into staple fibers, which are then baled. The usual mass of a bale can range up to 500 kg.

Staple fiber draw lines are up to 80 m long and produce from 20 to 250 t/d, the latter, of course only for high-volume products. Delivery speeds range from 150 to 300 m/min, with tow sizes up to 600 ktex and more [91]. Investment and manufacturing costs per ton per day are reduced considerably with increasing productivity of these draw lines [89].

Completely continuous installations with capacities of 12 – 15 t/d produce smaller lots. They are supposed to be superior to the usual tow band installations in terms of investment and manufacturing costs, but they produce fibers with three-dimensional crimp. Whether such fibers can be spun in blends with natural fibers and whether fabrics produced from such yarns will be acceptable in the marketplace remain open questions [89].

Types of Fibers, Properties, and Uses. Polyester staple fibers encompass the broadest product spectrum of any fiber. They can be found in all areas of application [37, 92–94]. They are used in apparel for overcoats, jackets, leisure- and sportswear, ladies' outerwear, men's suiting, work and protective clothing, children's wear, underwear, and sleepwear. In home furnishings, they range from drapery and curtain fabrics, through furniture coverings, pillows and pillow stuffing, table and bed linen, to wall and floor coverings. They have a whole host of industrial end uses along with filament yarns, spunbonded products, and monofilaments. A few examples of applications are in filtration, automobile interiors, geotextiles, and material for the sewing trade.

Yarns made from PETP fibers can be processed without reservation in weaving and knitting as well as in tufting. The fibers are completely suitable for processing as unblended yarns (100 % PETP), as well as in blends with cotton, wool, silk, cellulosic man-made fibers, acrylic fibers, and many more.

Of all polyester fibers, *cotton types* have the largest market share. These are processed into blended yarns, and these in turn into blended articles. These contain cotton, viscose, or modal fibers in what are today considered the "classical" blend ratios of 65 : 35 or 1 : 1 (PETP to cotton) and in other ratios.

The stress – strain curve of cotton types is shown in Figure 4. Its initial slope corresponds approximately to that of cotton. Their finenesses of 0.4, 0.9, 1.3, and 2.4 dtex, and the major one of 1.7 dtex, at cut lengths of 30 mm and 38 mm are matched to cotton.

Figure 4. Stress – strain curves of PETP cotton type staple fibers
———— Cotton
– – – – – PETP cotton type (normal shrinkage)
— · — · — PETP cotton type (low shrinkage)
· · · · · · · · PETP sewing thread type

Fibers with normal high shrinkage and others with reduced shrinkage are available and used to vary the hand and appearance of textile fabrics over a wide range. With the additional pos-

sibilities offered by the choice of fineness and weave construction, the textile processor can exert a major influence on the permeability of, for example, tent, overcoat, shirt, and blouse fabrics. In comparison to wool types of polyester fiber, dyeing of highly oriented cotton types is somewhat slower but, like the former, presents no problems.

Special cotton-type fibers, which are also offered as continuous tow for processing on stretch – breaking converters, are intended for sewing. These fibers are especially highly drawn and, therefore, have the highest moduli (resistance to elongation) and tenacities.

Wool types are intended primarily for processing in blends with wool. The major blend ratio is 55 : 45 (PETP to wool). The stress – strain curves of these fibers are matched to that of wool (see Fig. 5) by tensionless heat-setting during fiber manufacture, as described in Section 2.1.4. Shrinkage, therefore, is low, and dyeability is optimum. The spectrum of fineness and cut length ranges from 1.7 dtex (38 mm) to 6.7 dtex (120 mm). Wool types are also available as continuous tow for processing on cutter – converters.

Figure 5. Stress – strain curves of PETP wool types
—— Wool
– – – – PETP wool type (normal)
· · · · · PETP wool type (low pilling)

The so-called pilling phenomenon, which occurs in blends with wool, has been responsible for considerable developmental cost. Small balls or pills are formed on the surface of textile fabrics during use. Suitable fibers have been developed to solve this problem [59], [93]. Their special structure eventually causes the fibers anchoring the pill to break. In this manner, the pill disappears soon after it is formed.

A third group consists of the *fiberfill types* commercially available as staple fibers but also as continuous tow. These fibers are used both in apparel (primarily for heat insulation) and in home furnishings (primarily in pillows, cushions, and bedding). Their crimp is two- or three-dimensional. To improve the hand of fiberfill, such fibers are often provided with a special finish, based primarily on silicone. The range of linear densities of these fibers is between 1.5 and 14 dtex at a cut length of 30 – 80 mm (most common length, 60 mm). This group also contains high-shrinkage fibers with a shrinkage at the boil of 50 %.

In home furnishings and automobile interiors, *polyester carpet types* are used. These also include poly(tetramethylene terephthalate) fibers, see Section 2.4.1 (→ Polyesters, → Floor Coverings). Carpet fibers based on PETP are used as both normal and high-shrinkage types in home furnishings and in needle-punched felt. Such fibers are also made with various cross sections; their finenesses and cut lengths range from 6.7 dtex (135 mm) to 20 dtex (150 mm). An essential characteristic of polyester floor coverings is that their mechanical properties are unaffected by moisture.

Special types of PETP staple fibers have secured a place in the market. Some can be dyed in an open vessel without carrier to deep shades [68]. Such staple fibers and tows meet special requirements of environmental protection where wool blends have to be used (carriers) and HT dyeing is, therefore, excluded. These fibers exist as standard types and as pill-resistant tows. Cationic dyeable staple fibers are used in relatively small amounts in the wool area and in polyester carpets.

Since the mid 1970s,flame-retardant PETP fibers have rounded out the product spectrum [73]. These fibers are used in apparel and, especially, in home furnishings. They meet legal requirements and even exceed them in some cases. For these, PETP copolymers with phosphorus compounds have proved particularly useful. Fibers of this type combine the comfort expected of unmodified PETP fibers with modern safety requirements. They are distinguished by deep dyeability with disperse dyes. Because of their diverse applications, these fiber types

are available in finenesses and cut lengths from 1.7 dtex (38 mm) to 13 dtex (150 mm).

2.3.2. Continuous-Filament Yarns for Apparel and Home Furnishings

Special Features of the Manufacturing Process. Poly(ethylene terephthalate) that is to be spun into continuous-filament yarn for apparel generally exhibits an intrinsic viscosity [η] of 0.70 – 0.75 [37]. It must be highly purified, especially when used in high-speed spinning, which is often the case. The polymer must also be dried carefully to $< 0.01\,\%$ H_2O.

As in staple fiber units, the spinning positions of a spinning machine are aligned in a row. Quenching is mostly done by a transverse air flow with several spinnerets in a single shaft so that all filament bundles are affected uniformly. At the lower end of the spinning shafts, the filament bundles are individually combined into yarns while finish is applied to them. Finishing with a perforated yarn guide has been generally adopted. Below the spinning shafts, the yarns are usually drawn off by godets, the circumference and revolutions of which determine the spinning speed; the yarns are then wound individually on bobbins [37].

Originally, spinning speeds were 500 – 1500 m/min. The as-spun yarn was amorphous and characterized by an orientation birefringence Δn of $(3-10)\times 10^{-3}$, a so-called *low orientation yarn* (*LOY*) [53], [95]. The as-spun yarn was drawn by passing it, with friction, over heated pins in the draw zone and then additionally, with surface contact, over a hot plate. This process was replaced by drawing on heated rolls with several wraps [37]. For heat-setting, the delivery roll of the set of draw rolls was also heated but at considerably higher temperature. Final drawoff was by a third pair of rolls. The drawn yarn was wound on a twister (draw twisting) or on a winder (draw winding); frequently it was then twisted, heat-set, and rewound. Such units, which involve slow spinning and separate drawing, are still operating but are probably no longer being built.

Improvements in winding frames for drawn yarn led to the next development, spin drawing . In this process, a set of draw rolls is mounted below each spinning shaft. The as-spun yarn is drawn down at ca. 700 m/min and finally wound at ca. 3000 m/min. Winders developed for high-speed spinning in 1983 permit drawing down at speeds up to ca. 4000 m/min with final windup speeds up to 6000 m/min [87]. This process is highly cost-effective, and product quality is good.

In a variant of the spin-drawing process, the draw rolls are mounted near the spinneret at the point where the filaments have just attained their final fineness and are still warm [96]. This process, too, is rated highly for cost and quality of product.

Spinning speeds have gradually been raised to 2800 – 4500 m/min to increase productivity of the spinning units. The result has been production of *partially oriented yarn (POY)* [53], [95]. These yarns are less sensitive because of their inherent slight crystallinity and require less drawing. Drawing can now be combined with texturing into a single process, with considerable savings in investment and operating costs [97].

Drawoff rolls or godets are not required in high-speed spinning, and drawing-off can be left to the winder; however, special measures must be taken to match the spinning tension to the optimum (mostly lower) windup tension [87].

Yarn spun at higher speed and then drawn takes up dye more readily; because it is more highly oriented, postdrawing is lower and entails less additional crystallinity. Material spun at very high speed is, moreover, said to have an especially loose structure, with fewer large crystalline regions, even after drawing [53].

Commercial high-speed spinning has become possible only through the development of suitable winders, which can also be used for as-spun yarn. They can go as high as 6000 m/min and, for experimental purposes, up to 10 000 m/min [98].

In the speed range of 3000 – 4000 m/min, productivity no longer increases substantially with spinning speed. Hence, yarn spun at 2800 – 4000 m/min has been adopted as the starting material for draw texturing [95]. Therefore, additional investment in increased spinning speed is probably not worthwhile [99]. Efforts have been directed at reducing spin orientation and thus increasing draw ratio and productivity. For example, a heating tube below the spinneret reduces spin orientation [100], as do minor additions to the polymer of low-viscosity polymers

[101] or components with slight cross-linking action [102].

The drawing process is combined with texturing in draw texturing to produce textured yarns from material spun at high speed. In this process, the yarn is drawn in the texturing zone on the first heater of the texturing unit, i.e., between the delivery rolls and the twister. This places stringent requirements on the as-spun yarn. Its structural properties, such as orientation and crystallinity, must be uniform to ensure uniform dyeability of the end product. In addition, the as-spun yarn must not have any defects such as broken filaments. In most cases, the yarn is additionally heat-set on a second heater in the texturing unit with a 7 – 14 % contraction in length. This setting process reduces the crimp elasticity of the yarn, which is then dimensionally stable.

The major problem in the manufacture of textured PETP yarns is uniform dyeability. The many process steps and, hence, variables require special attention during manufacture. Total testing costs are high.

A smaller fraction of PETP filament yarns for apparel is processed without texturing. Flat yarns are obtained by the old process of separate spinning and drawing mentioned previously, as well as by spin drawing. More recently, flat yarns have also been spun at high speed [48], [53]. Several processes, such as high-speed spin drawing and warp drawing [103], [104], can accomplish this economically and with high product quality.

Because PETP yarns spun at 6000 m/min still have flat stress – strain curves, they cannot be used as is [95]. Thermal treatment in the spinning shaft, e.g., a heating zone in the shaft, helps increase their orientation and crystallinity [105], [106]. The stress – strain behavior of this *highly oriented yarn (HOY)* then suffices for several special applications. At still higher spinning speed, the sheath – core effect of orientation and crystallinity can exert a negative influence [53], [107].

Types of Continuous-Filament Yarn, Properties, and Uses. Continuous-filament yarns are products of the man-made fiber industry that can be converted directly to textile fabrics, i.e., without intermediate processing. Whereas staple fibers are produced by first cutting crimped filaments which then must be spun into a yarn, possibly in mixtures with other fibers, in a relatively expensive process, filament yarn is available immediately.

Filament yarn is offered flat, i.e., with silk-like, or variously crimped textures; thus, it provides opportunities to change the hand, bulk, and optical appearance of downstream goods and to accomodate styling requirements in apparel and home furnishings, which far exceed the range attainable with natural fibers [37], [92][93][94].

Partially oriented yarns (POY) have, since the introduction of high-speed spinning technology (see Section 2.1.2), led to successful intermediates for internal fiber production as well as to salable products. These filament yarns are spun and wound at speeds of ca. 3000 – 4500 m/min. They are precursors for pirn drawing (cops drawing), warp drawing (→ Fibers, 3. General Production Technology), as well as warp drawing – sizing or draw texturing. Most POY products with a fineness of 300 dtex and 32, 34, or 36 filaments per yarn (dtex 300 f 32, etc.) are produced for draw texturing, which is the largest end use.

Flat Yarns. For direct textile processing in weaving and knitting, suitable flat *fully oriented yarns (FOY)* are available on pirns, bobbins, or as warp beams. They are sold with round, trilobal, triangular, or even octalobal cross sections with an individual filament fineness of 2 – 5 dtex and a yarn fineness of 22 – 167 dtex.

Figure 6. Stress – strain curve of highly oriented filament yarns (HOY)

Pirn (cops) material intended for weaving and warp knitting is produced "classically" with twist from LOY or from POY. Material in bobbins, on the other hand, is used exclusively in weaving and comes primarily from one-step processes such as spin drawing or high-speed spinning (4000 – 6000 m/min) (see Section 2.1.2).

The fineness of individual filaments made by this latter process ranges from 0.6 to 3 dtex. These HOY yarns are distinguished by uniform dyeability. A stress – strain curve, which, in contrast to standard yarn, exhibits higher tensile elongation, is shown in Figure 6. Warp beams, finally, are produced by the warp-drawing process from POY exclusively for warp knitting. For weaving, the warp draw – sizing process is used.

Textured Yarns. The major application for textured yarn, primarily false-twist textured, is in knitting and weaving for apparel. Air-textured yarn, on the other hand, is used predominantly in home furnishings and is processed by weaving.

False-twist textured yarns are draw-textured, starting with POY, mostly by the friction process, but in some cases by the spindle process. Their linear density is 50 – 200 dtex (singles yarn), with an individual filament fineness of 1.25 – 5 dtex. The round cross section of POY filaments is distorted by draw texturing. However, special yarn types are produced with a triangular profile, which is preserved during draw texturing. This type of individual filament cross section imparts a special luster, almost a glitter, to textile fabrics. The linear density of most false-twist textured yarns now used in knitting and weaving is ca. 167 dtex. Fine yarn down to 50 dtex/40 filaments is used in ladies' blouses, for example.

Air-textured yarn can be made from either POY or FOY. With POY, a drawing step precedes air texturing on the texturing machine, whereas FOY is textured directly. In this process the filament cross section, usually round, is preserved. The linear density of such yarn is 200 – 3000 dtex for single yarn, which is appropriate for its primary use in home furnishings. The fineness of individual filaments is 2 – 3 dtex.

Special Types. The extensive product line of continuous-filament yarns includes many special types. Examples of interesting new developments are filament yarns with staple yarn character, i.e., filament yarns with the less regular and bulkier structure of staple yarns, which is achieved by the type and arrangement of individual filaments. In some cases, free fiber ends even protrude from the yarn.

A large variety of properties is possible today. Among the most important are yarns with high bulk character, which is achieved by differential shrinkage of individual filaments. The properties of such yarns, however, are closer to flat yarns. Other yarns are formed by cotexturing different types of individual filaments. These approach staple yarns, even with regard to the comfort of clothing made from them.

Extremely low fineness filaments with individual counts down to 0.1 dtex (produced by splitting thicker filaments) or 0.6 dtex (spun directly) are used in textiles with the appearance and feel of buckskin.

In differential dyeing cationic dyeable yarns are used in addition to normal disperse dyeable filament yarns. When yarns are made from blends of disperse dyable individual filaments and cationic dyeable ones, they may be dyed in different colors.

Flame retardancy in home furnishings, especially in drapes and curtain fabrics, is achieved with filament yarns that consist of modified PETP. By inserting a phosphorus compound into the fiber molecule, the flame retardancy of such yarns is permanent and cannot be removed in washing or dry cleaning.

Finally, filament yarns with permanent antistatic properties are available. In general, however, the surface conductivity required for processing and for some end uses is achieved by applying finishes.

2.3.3. Continuous-Filament Yarns for Industrial Applications

Special Features of the Manufacturing Process. Filament yarns for industrial use are generally spun from higher molecular mass PETP, which is the only way to achieve high strength. For low-fineness, high-tenacity yarn (final fineness < 1000 dtex) PETP with an intrinsic viscosity $[\eta]$ of 0.75 – 0.80 is used; for coarse, high-tenacity yarns (final fineness ≥ 1000 dtex), the intrinsic viscosity $[\eta]$ of PETP is 0.95 – 1.05. Such molecular masses are achieved either by continuous polycondensation with direct spinning or, preferably, by postcondensation in the solid state [37].

During condensation in the melt, COOH end groups, which catalyze hydrolytic degradation of PETP in the melt, are formed in the polymer and can disarrange the structure in the final product. These end groups can be protected with carbodiimides [70] or similarly acting sub-

stances, which are added to the polymer in small amounts prior to spinning. No COOH groups are formed if solid-state condensation is carried out in a vacuum or under a protective gas and at temperatures below the melting point. Care must be taken, however, that the polymer does not absorb water during storage or during transportation from the condensation to the melting equipment.

Polymer with a high viscosity requires a rather high spinning temperature, e.g., ca. 290 °C for fine yarn and ca. 310 °C for coarse yarn [37]. To minimize thermal degradation of the melt, the lines carrying melt from extruder to spinneret must be as short as possible. Also, the melt in the distribution lines after the extruder is kept relatively "cold" and warmed to the higher spinning temperature only in the spinning pack [108].

Fine, high-tenacity yarn has a linear density similar to that of textile yarn. For this reason, it is spun on a similar machine. The yarn is either spun and drawn in separate process steps or spin-drawn continuously. The spinning speed for fine high-tenacity yarn in the two-step process is approximately 1000 m/min and 500 m/min and higher during spin drawing. The draw ratio is ca. 5; the yarn is usually allowed to shrink ca. 10 % during heat-setting at a hot roll temperature of ca. 240 °C. The delivery speed of the drawing machines is ca. 700 m/min, but during spin drawing, it is substantially higher (ca. 2500 – 3000 m/min).

A special, high-volume variant of fine, high-tenacity yarn is sewing yarn. By plying, twisting, and renewed heat-setting, throwsters turn this yarn into sewing thread, whose most important characteristic is the sewing length achievable. The goal is sewing yarn that needs no further plying and twisting to make it comparable in processability to sewing thread of staple fiber.

During spinning of particularly viscous polymers for coarse industrial yarn, very high drawing forces develop in the filaments. These forces can be relieved by delaying filament cooling with the aid of a heating tube directly below the spinneret, which reduces spin orientation and equalizes the structure of the filaments [100], [109]. In this way, noticeably higher final strength can be attained [110].

Coarse high-tenacity PETP yarn is produced either in one step by spin drawing or in two steps by spinning and further treatment as a warp. During spin drawing, the spinning speed is ca. 700 m/min; when spun on bobbins for warp processing, it is ca. 700 – 1000 m/min. Yarn has been spun at much higher speed, in which case the disturbing influences mentioned previously are compensated in other ways [111].

The spin-draw machines for coarse high-tenacity yarn resemble those for fine high-tenacity yarn except that some parts are even more massive [94]. Because of the high operating speed (up to 4000 m/min) the residence time on heat setting rolls and beyond is short. Therefore, preparing low-shrinkage material by spin drawing is difficult; however, the strength that can be achieved is considerable.

In the draw-line process, a warp of yarn is drawn in two steps and then heat-set. After the last set of rolls, which determines the setting shrinkage, the yarn is wound on individual bobbins. The delivery speed of such draw lines is 120 – 300 m/min, with a productivity of 4 – 10 t/d.

The ability of the end product to shrink and its shrinkage force can be reduced, both in spin drawing and in warp processing, by permitting shrinkage in the heat-setting step. This increases elongation of the yarn at loads important in practical applications. The much higher residence time of the yarn in postdrawing and setting in the warp process leads to lower residual shrinkage at equal relative elongation of the end product (relative elongation being the elongation at a given load). Inversely, at equal residual shrinkage, the relative elongation of the product from the warp process is lower. These relationships are influenced further by the polymer used, the spinning process, and the drawing conditions.

In certain end uses, coarse industrial PETP yarn must exhibit good adhesion to rubber. For this purpose, an appropriate adhesive finish is applied during spinning or in warp processing prior to heat-setting. This finish may contain epoxy compounds (Epikote) or similarly acting material.

Industrial Yarns, Properties, and Uses. Of the three product forms used industrially, i.e., high-tenacity filament yarns, spunbonded products, and monofilaments, the filament yarns have by far the broadest application [37], [92][93][94]. This ranges from the building in-

Table 8. Filament yarns for industrial end uses

Types	Shrinkage in hot air at 200 °C, %	Fineness, dtex	Number of filaments	Filament fineness, dtex	Tenacity, cN/tex	Elongation, %
Yarns for sewing threads, normal shrinkage	17 – 18	74 – 455	24 – 96	3.1 – 4.7	68 – 70	12 – 13
Yarns for sewing threads, low shrinkage	7	49 – 940	16 – 200	2.5 – 4.7	68 – 70	16 – 17
Fine yarns, normal shrinkage	18 – 19	280 – 940	48 – 200	3.3 – 5.8	65 – 70	12 – 14.5
Fine yarns, normal shrinkage (spun-dyed black)	19 – 22	550 – 940	50 – 100	9.4 – 11	66 – 69	19 – 22
Fine yarns, low shrinkage	4 – 14	140 – 550	24 – 96	5.8	60	21
Coarse yarns, normal shrinkage	15.5 – 22	1100 – 1670	100 – 200	5.5 – 11	72 – 73	13 – 15.5
Coarse yarns, normal shrinkage (spun-dyed black)	15.5 – 22	1100 – 1670	100 – 200	8.4 – 11	66 – 72	12.5 – 13.5
Coarse yarns, low shrinkage	3.5 – 5.0 (7.5 – 8.5)∗	1100 – 1670	200	5.5 – 8.4	72 (73 – 75)∗	16.5 – 17.5 (11.5 – 12.5)∗
Coarse yarns for tire cord	10 – 18	1100 – 1400	200	5.5 – 7	75	12
Coarse yarns (plied fineness)	22	2200 – 11 000	400 – 2000	5.5	other values depend on single yarn	

∗ With adhesive finish.

dustry through machine and motor vehicle construction, chemistry, mining, agriculture and forestry, transportation, sporting goods, protection of the workplace and the environment, to apparel and home furnishings. Such yarns are offered on the market in three major categories: sewing yarn, fine yarn, and coarse yarn. Depending on end use, these yarns are employed either as normal-shrinkage or low-shrinkage types. In addition to fine and coarse white yarns, spun-dyed black types are also available. The extraordinarily broad product line is rounded out by plied fineness of coarse filament yarns. For an overview see Table 8.

Sewing Yarns. The value of sewn textiles, particularly their appearance and durability, depends to a large extent on seam performance. To best complement textile design and construction, the seam must meet many requirements, the most important of which are neat appearance, high tenacity and abrasion resistance, high lightfastness (especially to ultraviolet radiation), resistance to chemicals, and washfastness. In addition, good sewability is significant for the sewing yarns; this is defined as achieving a high sewing length at high sewing speeds without yarn breakage. All these requirements are met or exceeded by fine denier, high-tenacity PETP filament yarns. They have performed well alongside PETP staple yarns and PETP stretch-broken yarns in 100 % PETP sewing yarns as well as in core-spun yarns.

Sewing Yarns with Normal Shrinkage. Filament yarns with normal shrinkage are suitable for 100 % PETP sewing yarns, which must be heatset (Table 8). Sewing threads prepared from them are used especially in high-performance areas, e.g., safety belts, cushions, leather shoes, luggage, and handbags.

Sewing Yarns with Low Shrinkage. Low-shrinkage filament yarns are offered in a broad range of finenesses (Table 8). The largest end use is in core-spun yarns. By spinning a sheath of cotton, viscose, or other polymeric staple fiber around a PETP filament core, the properties of both fiber types are combined. The sheath assures sewability; the core, mechanical efficiency. Such yarns meet high requirements of aesthetics, dyeability, and temperature resistance.

Fine Filament Yarns. Both normal- and low-shrinkage fine filament yarns are available for

general use. Filament yarns with normal shrinkage are offered as white or spun-dyed black types. Both types are preferred in lashing straps, tapes, belts, ropes, nets, and fire hoses.

Low-shrinkage fine filament yarns are offered only in white (Table 8). They have a wide range of applications, extending from base fabrics for PVC or rubber coating for tarpaulins, membranes, containers, awnings, and tent roofs, through conveyor belts, V-belts, hoses, filter fabrics, and drying screens for paper making to sailcloth. Its use in sailcloth demonstrates the ability of PETP to meet the requirements of low mass, high tenacity, and uniformity, as well as resistance to UV light, chemicals, water, and mildew.

Coarse Filament Yarns. Coarse yarns, like fine yarns, are offered with either normal or low shrinkage (Table 8). Yarns with normal shrinkage are available in white or spun-dyed black versions. White yarns, analogous to the corresponding fine yarns, are intended for lashing straps, belts, ropes, nets, hoses (especially pressure hoses), and safety belts. The situation is quite similar with respect to the black types, which are used primarily in safety belts and lashing straps.

Low-shrinkage coarse filament yarns, which are offered exclusively in white, have equally wide-ranging applications, such as base fabrics for PVC or rubber coating for tarpaulins, membranes, containers, awnings and tent roofs, hoses, filter fabrics, belts, conveyor belts, V-belts, and drying.

An especially interesting end use for low-shrinkage, high-tenacity, adhesively finished filament yarns is in automobile tires. The properties of such yarns make them highly suitable for the carcass of radial tires. Tires with these yarns no longer exhibit the disturbing phenomenon of flat spotting, observed in nylon-reinforced tires. (Flat spotting is the formation of an elliptical footprint in the tire during standing, resulting from molecular deformation of nylon because of its low glass transition temperature. It causes a bumpy ride until the tire warms up.) Since the early 1960s, much effort has been expended to solve the problems of PETP tire-cord material. In addition to rubber adhesion, these included the hydrolytic stability of PETP. High-tenacity filament yarns for tires are rather low in shrinkage. They have high moduli, exhibit high flexural strength, and thus produce little heat during mechanical loading. They, therefore, have all the prerequisites to utilize fully the high chemical stability (resistance to hydrolysis) provided by extremely low concentrations of COOH groups. Solid-phase polycondensation combined with chemical capping of the majority of any still-existing COOH groups (see Section 2.2.1) makes possible the high stability of the tire cord.

The high-tenacity, coarse-filament single yarns discussed so far are complemented for many end uses by a series of plied yarns. These include some that are adhesively finished for use with rubber, others that have low-shrinkage like the single yarns, and still others that have normal shrinkage. Their finenesses extend up to 11 000 dtex. These yarns are intended for use in the coating sector as well as in straps, belts, ropes, nets, and hoses.

2.3.4. Spunbonds

Special Features of the Manufacturing Process. Spunbonded products are consolidated random layers of 2- to 10-dtex continuous filaments [112]. They are produced as continuous sheets up to 5 m wide in a continuous process from polymers of average intrinsic viscosity ($[\eta]$ ca. 0.7). Their unit weights range from 20 to 500 g/cm^2 (→ Fibers, 3. General Production Technology).

A spunbond production line usually consists of several rows of spinnerets with mutually displaced spinning packs. Each filament bundle is accelerated by a draw tube under the spinneret to a final speed of $\geq$ 5000 m/min and thus is drawn [113]. Spreading devices open the filament bundle and lay the filaments down on a moving belt in overlapping random patterns. Various designs are known for these spreading devices; i.e., mechanical, pneumatic, and electrostatic [112].

Properties of the filaments are the same as those of filament yarns spun at high speed: tenacity ca. 3.5 cN/dtex, break elongation ca. 70 %, and shrinkage at 200 °C ca. 3 %. The orientation is characterized by a birefringence Δn of ca. 100×10^{-3}, and the degree of crystallinity is ca. 40 %.

The loose filament web, laid down as uniformly as possible, is then consolidated by using various processes singly or in combination, such

as needle punching, calendering, and bonding. For certain applications, the web must be made thermally stable by additional heat-setting.

Spunbonded Products, Properties, and Uses. Polyester spunbonds are available in unit weights of 20 – 500 g/m^2 and in widths of 1 – 5 m. The consolidation discussed in the preceding section via needle punching, bonding, or calendering requires, in addition to PETP and suitable binders, the use of polyesters of lower melting point or even of PETP fibers with a sheath of a different polymer. Polyester spunbonds are offered commercially under various *trade names:*

Asahi	Asahi Kasei
Colbond BV	Coltron
EniChemFibre SpA	Terbond-Spun
Hoechst	Trevira-spunbond
Lutravil	Lutradur
Reemay, Inc.	Reemay
Rhône-Poulenc	Bidim
Teijin	Unisel
Toray	Axter
Toyobo	Toyobo Volans
Unitika	Marix

Lightweight webs (20 – 50 g/m^2) are available with individual filament counts of 2 – 3 dtex. They are used as cover webs in sanitary products and in horticulture.

Nonwoven products (50 – 130 g/m^2) have filaments with individual finenesses of 4 – 5 dtex. Their end uses are in construction and in shoe caps.

Materials with unit weights of 130 – 500 g/m^2 and individual filament finenesses up to 10 dtex are intended especially for use in construction (e.g., carriers for asphalt sheets for roofing), needle felts, embossed PVC coatings, underground construction, hydraulic engineering, and road building.

In addition to their large use in construction, polyester spunbonds are already being used successfully in automobiles (e.g., trunk linings) as well as in protective clothing and for environmental protection (covering of storage basins).

Web properties depend predominantly on the often different technologies for web production (laydown and bonding). No systematic data exist up to now that relate web structure to various end uses. However, in general, needle-punched webs are bulky, whereas thermally bonded webs are thin. Web strengths are ca. 2 – 4 N g^{-1} m^{-2} throughout (measured on strips 5 cm wide). Break elongations are 60 – 100 % for needle-punched webs, 20 – 60 % for bonded and needled webs, and generally < 30 % for thermally bonded webs.

2.3.5. Monofilaments

Special Features of the Manufacturing Process. In the production of PETP monofilaments, polymers with intrinsic viscosities $[\eta]$ of 0.7 – 0.9 are used. Polymers of higher viscosity are often brought to their required value by solid-phase condensation. Because these polymers then have a lower content of COOH groups, they have advantages for use in hydrolysis-resistant monofilaments with increased hot – wet durability. Occasionally, the COOH end groups of the polymers are also protected chemically.

Monofilaments with final thicknesses of 0.03 – 2 mm are spun in air, cooled immediately in water, then drawn, heat-set, and packaged on a directly connected draw line [114]. Each extruder usually has its own spinning head and, accordingly, its own draw line. Various designs are recommended for spinning heads and spinnerets, such as circular spinnerets and spinnerets with straight rows of holes [115]. Feed for each spinneret hole should be the same. A few centimeters below the spinneret, the filaments enter a water bath, whose temperature is above the glass transition temperature of PETP (70 °C). The filaments are cooled but remain soft. In the bath, they change direction, are brought out of the bath as a warp sheet, and are drawn off by a set of rolls at a rate of less than 100 m/min. The filaments have no spin orientation.

The first draw almost always takes place in water at 90 – 95 °C; the second draw, also takes place in a water bath, a higher boiling liquid, or a heater tunnel. Die plates are sometimes used for more accurate adjustment of the thickness. Heat-setting occurs in a heater tunnel, usually at 130 – 180 °C. Depending on the type desired, more or less shrinkage is permitted and the total draw ratio (ca. 1 : 4 to 1 : 6) is selected. At the end of the roll train, the monofilaments are taken up on individual bobbins on a creel.

In almost all applications of PETP monofilaments a uniform diameter is the most important mark of quality. Tolerance of ± 3 % is re-

quired; if the process is carefully controlled, it will often be less. Additional quality requirements are smooth surface and, if necessary, uniform cross section. Textile properties of a given type must always remain constant, especially shrinkage tension and shrinkage. In monofilaments with improved resistance to hydrolysis, the residual strength after prolonged use should be preserved uniformly.

Types of Monofilaments, Properties, and Uses. Monofilaments are produced with diameters of 0.034 – 2.00 mm These are thick filaments (the finenesses corresponding to these diameters are 12.5 – 43 000 dtex) and are, therefore, often called wires. A broad spectrum of types of PETP monofilaments is found commercially in woven fabrics and zippers. These end uses place strict requirements on uniformity of diameter and properties, and especially on stress – strain behavior and shrinkage. The mechanical properties of typical PETP monofilaments are evident from the stress – strain curves in Figure 7.

Figure 7. Stress – strain curves of typical PETP monofilaments
——— Finest monofilament (0.055 mm diameter)
– – – Monofilament for weaving (weft type)
····· Monofilament for zippers

Monofilaments for weaving are used in the building industry in interior construction and interior installation. Other, often large, areas of application are paper machine sieves, safety belts, filter and screening fabrics, as well as conveyor belts. Fish nets, cordage, fishing lines, and medical applications all require the special properties of monofilaments for weaving.

The finest monofilaments, with diameters of 0.034 – 0.055 mm, have high elongation (see Fig. 7) and, at the same time, high shrinkage. Coarser wires range from 0.080 – 2.00. In addition, some wires have a rectangular cross section with diameters from 0.25 and 0.50 mm to 0.57 and 0.88 mm.

Monofilaments for weaving, especially for paper machine sieves are available as normal, hydrolysis-resistant, and chemically stabilized types. The most important representatives have high elongation (wires for the weft) or low elongation (wires for the warp) but low shrinkage.

Another important group comprises *zipper monofilaments*, with a diameter of 0.40 – 1.16 mm. This competes with polyamide wire. A major advantage with PETP monofilaments is that their stress – strain properties and shrinkage behavior can be varied to a great extent. Thus, zipper wires are available over a whole gamut of combinations from low, elastic extensibility with high shrinkage to high, plastic extensibility with low shrinkage. The majority of these types exhibit low, elastic extensibility and medium shrinkage at the boil.

In general, the combination of modulus and shrinkage properties of zipper wire and wires for weaving is determined by the special manufacturing process. It is chosen according to the load – time program and the thermal exposure of monofilaments during use. The ability to vary their properties so widely makes possible the adaptation of PETP monofilaments to any kind of processing and to any end use.

2.4. Other Polyester Fibers

2.4.1. Poly(tetramethylene terephthalate)

The polyester of terephthalic acid and 1,4-butanediol [*110-63-4*] is a comparatively old fiber polymer [40].

Because 1,4-butanediol has always been more expensive than ethylene glycol, poly(tetramethylene terephthalate) [*30965-26-5*], also called poly(butylene terephthalate) or PBT, remained more or less on the sidelines. Not until the middle of the 1960s

were special PBT products developed by several producers; the advantages of these products compared to PETP permitted use of the more expensive 1,4-butanediol [116]. Today, these PBT products have become well-entrenched in the marketplace.

Production of PBT is similar to that of PETP. Dimethyl terephthalate is transesterified and subsequently polycondensed, either batchwise or continuously. However, the catalysts used with PETP promote ring closure of 1,4-butanediol, leading to the potentially explosive tetrahydrofuran. Therefore, tetraisopropyl titanate [*546-68-9*], for example, is used as catalyst in both process steps.

Because the aliphatic sections of the molecular chains are longer and thus more mobile, the transition temperatures of PBT, *mp* ca. 230 °C and glass transition temperature ca. 25 °C, are lower than those of PETP. In addition, PBT crystallizes more readily than PETP. The PBT unit cell exists in two modifications. Of these, one is more extended, ca. 11 % longer, and reverts to the shorter one when unloaded. This is responsible for the better recovery of PBT products from stretching and bending.

Like PETP, PBT is spun on standard machines from the melt. Because of the lower glass transition temperature, formation of spin orientation not only occurs along the spinning path but continues into the drawoff and the windup. In addition, clearly recognizable crystallization of PBT occurs during spinning, which in turn also affects orientation. Properties of the as-spun yarn thus depend in a complicated manner on spinning conditions.

After the usual drawing and heat-setting, PBT has a flatter stress – strain behavior than PETP (Fig. 8). The permanent extension of a PBT product after straining, however, is much less (Fig. 9) [116]. For example, after a strain of 15 %, the permanent extension of PETP is 8.5 %; that of PBT, only 2.5 %. For this reason, PBT is particularly suited for carpet fibers, which must exhibit good recovery after loading. Unlike PETP, PBT can be dyed easily to deep shades at the boil without carrier because of its lower glass transition temperature.

In addition to its elastic behavior and easy dyeability, PBT has other favorable properties. For example, it tends to swell less than PETP. All these factors, taken together, make PBT an interesting raw material for textile zippers. Finally, because of their resistance to alkali, good abrasion resistance, and elastic behavior, PBT monofilaments are advantageously used in screen fabrics, which are constantly exposed to hot water or slightly alkaline media. In this way, fibers for carpets and monofilaments for zippers and screens have become products in which the more expensive polymer (PBT) pays for itself.

2.4.2. Poly(1,4-dimethylenecyclohexane terephthalate)

Fibers of poly(1,4-dimethylenecyclohexane terephthalate) [*25135-20-0*], PDCT, have been on the market since the late 1950s under the trade name Kodel II (Tennessee Eastman Company, United States) (see below).

The intermediates are dimethyl terephthalate (DMT) (Section 2.1.1) and 1,4-bis(hydroxymethyl)cyclohexane [*105-08-8*] commonly known as 1,4-cyclohexanedimethanol. This diol is produced by the two-step hydrogenation of DMT at 160 – 180 °C and high pressure in the presence of catalysts (→ Alcohols, Polyhydric, Chap. 2.7.). The diol can exist as either the trans or the cis isomer. By appropriate choice of reaction conditions, the trans – cis ratio can be adjusted to 7 : 3. To prepare the polymer, DMT is transesterified with the diol and after excess diol is distilled, polycondensation takes place in a manner analogous to PETP.

The polymer is transparent and amorphous. It crystallizes in the triclinic system. The crystalline density is 1.265 g/cm^3 for polymer with trans isomer and 1.303 g/cm^3 for polymer with cis isomer [117], [118]. Wide-angle X-ray diagrams of crystalline samples show a continuous transition of the trans crystal lattice to the cis crystal lattice with increasing cis – trans ra-

A) Drawn; B) Drawn and heat-set without clamping; C) Drawn and heat-set with clamping; D) Drawn, heat-set with clamping, plus heat-set without clamping
– – – – PETP; —— PBT

tio. The fiber density is 1.22 – 1.23 g/cm^3. Small-angle X-ray investigations show a fibrillar structure with lattice layers at an angle to the fiber axis.

The glass transition temperature of the polymer is 76 °C; in drawn and crystalline fibers, it can be as high as 100 °C. The melting point is 285 – 295 °C [92].

Compared to PETP, the tenacity of PDCT staple fibers is ca. 30 % less, with the same elongation at break. The abrasion resistance behaves similarly. The tensile or bending recovery of the fibers from equal deformation at room temperature, on the other hand, is greater for PDCT because of the higher glass transition temperature of the polymer [118]. The result is greater crimp stability of PDCT fibers and, hence, greater bulk of nonwovens and textile fabrics. Because of the higher glass transition temperature, however, PDCT fibers are more difficult to dye than PETP fibers. Therefore, the dyeing temperature for PDCT fibers must be increased or suitable carriers and dyes chosen.

Applications of PDCT fibers are in areas such as fiberfill and carpets that require especially high crimp stability and generally high recovery forces following deformation at room temperature. These fibers are also used in blankets and synthetic furs [118].

2.5. Uses

Staple fibers, continuous-filament yarns, monofilaments, and spunbonds of polyester are found in all major textile markets. Among the polyesters, poly(ethylene terephthalate) is the most important polymer. Apparel, such as outerwear or sportswear, as well as work clothing and protective clothing, could not be imagined without PETP fibers, either 100 % or in blends with other man-made or natural fibers. Similarly, PETP fibers are widely used in home furnishings, such as drapes and curtains, furniture covers, table and bed linens, cushions, pillows, and carpets.

Polyester products have been particularly successful in industrial markets. Here, they are encountered everywhere fibers can be used. In many cases, because of their properties, especially their relatively low density (ca. 1.38 g/cm^3), they have provided elegant and, at the same time, economical solutions to problems. Examples are sewing thread, tarpaulins and awnings, safety belts, V-belts, tire cord, zippers, woven screens, geotextiles, roofing sheets, or book covers.

The extremely high performance of PETP is reflected in the breadth of end uses [37], [59], [69], [92, 93], [119], [121]. This performance is based primarily on two properties of the fiber products: the dimensional stability of the textiles made from PETP under mechanical and thermal stress, and their ease of care. Both properties are primarily determined by the glass transition temperature which, depending on the chemical structure of the polymer and the degree of orientation and order, lies between ca. 70 and 100 °C (see Section 2.2.1, → Fibers, 2. Structure). The fibers can be crystallized at any stage of their manufacture and during further processing. This permits production of any desired shape.

Polyester fibers are available in all possible forms in which natural and man-made fibers exist and can be processed on equipment used to manufacture yarns, woven fabrics, knit goods, and even nonwovens. Grouped broadly, the forms of PETP are the following:

1) Staple fibers with a fineness of 0.4 – 20 dtex; short cut fibers, 6 mm length, fibers of 30 – 60 mm up to 150 mm; round or modified cross sections; crimped (except for flat cut fibers).
2) Textile continuous-filament yarns with a fineness of 20 – 200 dtex; individual filament fineness of 0.5 dtex (special types 0.1 dtex) to 5 dtex; flat, textured, or with staple yarn character; round or modified cross sections. The fineness of air-textured, continuous-filament yarns is 200 – 3000 dtex.
3) Fine high-tenacity continuous-filament yarns and yarns for sewing threads with a fineness of 50 – 940 dtex, with individual filaments of 3 – 10 dtex; flat with round cross sections.
4) Coarse high-tenacity continuous-filament yarns with a fineness of 1100 – 1670 dtex (plied fineness up to 11 000 dtex); individual filaments of 5 – 11 dtex; flat with round cross sections.
5) Spunbonds in widths of 1 – 5 m; unit weights of 20 – 500 g/m^2, with an individual filament fineness of 2 – 10 dtex.
6) Monofilaments with a diameter of 0.034 – ca. 2 mm; flat with round or modified cross sections.

2.6. Economic Aspects

Figure 10. World production of man-made fibers
Vertically hatched area = polyester fibers; Plain area = other synthetic fibers; Horizontally hatched area = cellulosic fibers
∗ Estimated.

World production of fibers increased from ca. 14.9×10^6 t/a in 1960 to 34.8×10^6 t/a in 1985. Natural fibers, essentially cotton and wool, contributed ca. 7.6×10^6 t/a of this increase, whereas man-made fibers contributed ca. 12.2×10^6 t/a [41], [120]. Production of man-made fibers has increased fivefold from 1960 to 1985. Because the fraction contributed by cellulosic fibers decreased, the increase in production of man-made fibers can be ascribed solely to synthetic fibers (Fig. 10).

From small beginnings prior to 1960, polyester fibers, essentially poly(ethylene terephthalate), attained a volume of 6.5×10^6 t/a by 1985. Their percentage of the production and consumption of all synthetic fibers tripled between 1960 and 1985 (Fig. 11) and is now almost 50 %.

Figure 11. Production of polyester fiber compared to all chemical fibers and to synthetic fibers
Plain area = PETP proportion of all chemical fiber production; Vertically hatched area = PETP proportion of synthetic fiber production
∗ Estimated.

The two most important fiber forms are staple fibers and filament yarns. For *staple fibers,* including tow and nonwovens (Fig. 12), the production of cellulosic fibers remained approximately constant between 1965 and 1985. During this time, production of polyamide and polyacrylonitrile fibers, the latter predominating, increased sixfold. The increase in poly(ethylene terephthalate) is about twice as great, i.e., twelvefold. As far as end uses are concerned, PETP fibers compete with other synthetic fibers only in a few limited areas. They are used mainly in areas previously reserved for natural and cellulosic fibers.

In *continuous-filament yarns,* including industrial yarns and monofilaments (Fig. 13), pro-

duction of cellulosic fibers has decreased. Even before the rise of PETP, polyamide yarns had a secure niche in the market; between 1960 and 1985, their production increased approximately threefold. The production of polyester yarns increased twentyfold to equal that of polyamide yarns. Little competition exists between the two; if any, it is in the industrial area. Here, too, polyester continuous-filament yarns have primarily penetrated areas previously dominated by cellulosic continuous-filament yarns or by spun yarns of natural fibers.

∗ Estimated.

Figure 13. World production of continuous-filament yarns (key fiber materials)
Vertically hatched area = polyester; Diagonally hatched, inclined to the right = polyamides; Horizontally hatched area = cellulose
∗ Estimated.

Understandably, a vast amount of industrial development work and capital was required to build such enormous PETP fiber production. Sample figures are available for the early years of the PETP fiber, Terylene [38]. Large capital reserves were needed to maintain production during occasional wide swings in the market. For this reason, only large chemical companies were and are in a position to operate PETP fiber plants. A selection of trade names and producers follows [119]:

Allied Polyester (Allied, United States)
Dacron (Du Pont, United States)
Diolen (Enka, Federal Republic of Germany)
Fortrel (Celanese, United States)
Grilene (Emser Werke, Switzerland)
Grisuten (German Democratic Republic)
Kodel (Tennesee Eastman Co., United States)
Tergal (Rhône-Poulenc, France)
Terital (Montefibre, Italy)
Terlenka (Enka, The Netherlands)
Tersuisse (Viscosuisse, Switzerland)
Terylene (ICI, United Kingdom)
Teteron (Teijin, Toray, Japan)
Trevira (Hoechst, Federal Republic of Germany, United States)
Wistel (Snia Viscosa, Italy)

2.7. Polyester: Summary and Future Prospects

Properties. The following properties are responsible for polyester fibers being used in all areas where fibers are applied:

1) the extremely broad range of mechanical properties of staple fibers and filament yarns,
2) their variable and easily adjustable shrinkage properties,
3) their ease of dyeing combined with high fastness properties,
4) their high chemical, solvent, and UV resistance,
5) the low flammability of even the standard polymer, which can be further improved by modification without significantly impairing other valuable fiber properties,
6) the deformability of the fibers and the fabrics made from them,
7) the ability to make these deformations (e.g., crimp, creases, and pleats) permanent,
8) the low moisture uptake and, hence, rapid drying,
9) the fact that most soil remains on the surface where it is easily removed with water or solvents.

These properties are largely insensitive to the presence of water at moderate temperature. Together, they are responsible for the dimensional stability and easy care of textiles made from polyester fibers.

Comparison with Other Man-made Fibers. Polyester fiber products, especially those from PETP, are used commercially in large amounts in all common fiber forms: staple fibers, filament yarns for textile and industrial applications, spunbonded products, and monofilaments. The plethora of products and broad spectrum of applications are not nearly the rule for other major synthetic fibers, e.g., nylon 6 and 66 polyamides or polyacrylonitrile.

Both nylon 6 and nylon 66 filament yarns are used worldwide, especially in textured yarns and as tire cord, as are nylon spunbonds and monofilaments. The same is true for staple fibers in carpets. However, polyamide fibers are not easy to heat-set, which limits their application in apparel mainly to woven and knit goods.

With polyacrylonitrile, the product with the highest volume is staple fiber. They are used in apparel, especially in knitting, and in home furnishings in weaving, as well as in carpets. The strong dependence of mechanical properties on the presence of moisture at elevated temperature (poor dimensional stability) makes these fibers unattractive for woven fabrics in apparel. Filament yarns and fibers for industrial uses are still specialty products. To some extent, however, they are very successful, for example, as asbestos replacement in fiber-reinforced concrete. Polyacrylonitrile monofilaments or spunbonds are not produced because of the problems presented by solution spinning (coagulation and residual solvent).

Polypropylene, like polyester, is available in all types of fiber and nonwoven forms. However, the relatively low temperature resistance and lightfastness, as well as shortcomings in dimensional stability under permanent load, limit the use of this polymer to special areas of apparel, home furnishings, and industrial applications. Dyeability problems are forcing the use of spin dyeing in the apparel and home furnishings sectors.

Future Process Development. Polyester fiber polymer for staple fibers, filament yarns, spunbonds, or monofilaments will continue to be made by condensation. It will, likewise, continue to be melt-spun through spinnerets; the as-spun material will be drawn in some manner; and the drawn material will be posttreated according to end use. Processes, that differ in principle from this scheme have not shown up. However, individual efforts are underway in many locations to further improve the quality of intermediate and end products, to make processes more economical, and to adapt the products to the frequently changing and sometimes even entirely new needs of downstream processors and end users [94].

For example, attempts are underway to improve *polymer uniformity* from plant to plant and over long periods of time by careful process control, e.g., via automation and self-regulation. Equipment changes and variations in the catalyst system as well as in the temperature – vacuum program should improve the economics of polymer production. The key to this is increasingly combining continuous polycondensation with spinning, i.e., direct spinning. This combination of process steps, not only here but in the entire production of polyester products, will do much to improve the quality and manufacturing cost of the end product. Finally, various polymer additives will impart novel properties to the end products.

The uniformity and purity of *staple fibers* are being improved by changes in plants, e.g., in the manner of quenching during spinning and in the machinery of the draw line. This work will also improve the economics of the entire process. Additionally, staple fibers and tows must be adapted to the constantly evolving processes and plants of downstream processors. These adaptations involve mainly crimp and finish. The changing market, which often differs from country to country, requires manufacturers to alter the balance of properties of their products accordingly. This will necessitate variations in machine settings and in the equipment of the draw lines. A distant goal of staple fiber process development is to spin at high speed and to draw and posttreat in one step.

Purity and especially uniformity of dyeing also head the list of quality requirements for *filament yarns for apparel and home furnishings.* They are being improved constantly by careful process control and automation. Pro-

ductivity should be increased by even higher spinning speeds, although considerable physical fiber problems and equipment problems remain to be solved. Work is underway in several locations.

With *filament yarns for industrial use*, the question is to adapt strength and shrinkage behavior permanently to the requirements of each downstream processor and end user, and to explore additional end uses. This work involves the polymer as well as the plants and processing conditions. It entails improving the economics of polymer production, spinning, and processing of as-spun yarn.

In *spunbonded products,* uniformity of textile properties and uniformity of thickness are important. They can be improved by careful monitoring and automation of the process. Constructional work on spinning, drawing, and laydown equipment should result in both better and lower cost nonwovens. The greatest effort, however, is to open even broader and different end use areas to spunbonds by varying such web properties as filament fineness, web thickness, unit mass, and type of bonding. Because spunbonds represent a relatively new type of product, this work is likely to be successful.

Monofilaments require as much uniformity as possible with respect to textile properties and thickness in all applications. Work is, therefore, underway continuously to improve the process by equipment changes and monitoring. Furthermore, much work is being done on varying the textile properties and the monofilament polymer to open up new end uses.

Future Applications. Based on the success of polyester *staple fibers* as a component of blends with wool, cotton, and other cellulosic and man-made fibers, their use especially in blends and also in 100 % articles is expected to increase. This expectation is supported by the outstanding wear comfort of clothing made from these mixtures [121]. Polyester fibers cause moisture given up by the skin to be transported away, through the clothing to the outside. New types of fibers with voids will reinforce this transport mechanism in the clothing and fiberfill sector and will permit further improvements in comfort. New developments, especially in dry-laid nonwovens, will open up further end uses for polyester fibers. In so doing, consolidation by binders will be replaced more and more by thermal bonding. The use of polyester carpet fibers is expected to broaden constantly because of the development of new fiber types and carpet constructions.

Development work will focus on new types of *filament yarns for apparel and home furnishings*, particularly further improvement in aesthetics and wear comfort. In silklike textiles, the trend to ever finer yarns and individual filaments, combined with variation in filament cross section, will continue. In heavier fabrics, however, filament yarns with the character of staple yarns will continue to find new markets.

High-tenacity polyester *filament yarns for industrial end uses* with optimum all-around balance of properties and relatively low cost will continue to be available between standard textile yarns and special high-modulus fibers for constantly growing, as well as new, areas of application.

Spunbonded products based on polyester will probably be used in the future in composite systems, to an even greater extent than now. Contributing to this will be further exploration of the possibility of widely varying their structure and their properties.

A considerable expansion of end use areas for *monofilaments,* especially into the industrial sector, is expected, based on the further replacement of other fiber and natural products, especially metals.

Future Economic Aspects. Figures 10, 11, 12, 13 present estimates of world production of man-made fibers in 1990. Overall, an increase is expected, which, in absolute terms, is only slightly less than that between 1980 and 1985 (Fig. 10). The fraction of polyester fibers as a percentage of synthetic fibers and of all man-made fibers will continue to grow, but no longer as rapidly (Fig. 11). Nevertheless, the fraction of polyester fibers is expected to reach 50 % of all synthetic fibers.

Among the staple fibers, polyester will increase somewhat more than products of other polymers (Fig. 12), while filament yarns of polyester will remain about even with those of polyamides (Fig. 13).

Table 9 shows the average yearly increases in consumption of all polyester fibers from 1985 to 1990 and beyond, as a whole and divided into in-

dividual fiber types. Staple fibers and monofilaments are expected to develop like the average of all polyester fibers, while filament yarns for apparel seem to be approaching saturation. In contrast, well above-average increases are expected for industrial filament yarns and especially for spunbonds. Whereas these two products represent only 5.4 and 1.7 %, respectively, of the volume of all polyester fibers, they are, nevertheless, highly interesting from an economic point of view.

Table 9. Estimated average annual growth in the consumption of polyester fiber and other types of fiber

Fiber	Growth, % per year	
	1985 – 1990	1990 – 1993
Staple fibers and tow	3.2	2.7
Textile filament yarns	2.2	1.5
Industrial filament yarns	4.4	3.4
Spunbonds	8.4	5.3
Monofilaments	3.3	2.4
All polyester fibers	3.0	2.4
Other synthetic fibers	1.6	0.8
All synthetic fibers	2.3	1.6
Cellulosic fibers	0.2	−3.8
All man-made fibers	1.9	0.7
Natural fibers	1.3	1.1
All fibers	1.6	0.9

For comparison, Table 9 also shows the average yearly growth rates of other fiber groups. At least until 1990, the consumption of man-made fibers will increase somewhat more than world consumption of all fibers. Cellulosic fibers are initially expected to remain about the same and then to decrease markedly, possibly because of displacement by competing polyester fibers. Synthetic fibers as a whole will grow much more than all fibers. Natural fibers cannot grow appreciably because little room can be found for expansion of land under cultivation. The increasing worldwide demand for fibers will have to be met to a greater extent by synthetic fibers [119].

Because the remaining synthetic fibers are expected to grow no more than all fibers, the most significant growth compared to other types of fibers will be in polyester fibers. The reason for this is their extreme versatility. By varying the polymer and the processing conditions, polyester fibers can be adapted to the manifold requirements of the marketplace.

Understandably, these estimates are uncertain. The global growth rates will undoubtedly vary from country to country and from sector to sector. They will also be subject to fluctuations in world economy, especially to those affecting the cost of polymer intermediates and the price of cotton. The effects of unpredictable changes in consumer preferences and, hence, in fashions also contribute to the uncertainties of these estimates.

Overall, however, estimates of the average yearly growth in consumption of various fiber types suggest that the producers of polyester fibers will have to continue to improve the quality of their existing products and to open up new areas of application by developing new products.

3. Polyurethane Fibers

Following the discovery in 1937 of the diisocyanate addition polymerization process by O. Bayer and co-workers [122], this principle was applied to the production of polyurethane (PUR) fibers. Hard PUR fibers, first developed to compete with nylon 66, are no longer important. On the other hand, the same principle of synthesis was successfully applied to the manufacture of highly elastic yarns [123], [124].

Synthetic high-polymer fibers containing at least 85 wt % of segmented polyurethane are called *elasthane* [125]; the term *spandex* is used in the United States and in this chapter.

Spandex fibers are characterized by high elongation and elasticity. Like rubber yarns (elastodiene fibers), they belong to the class of elastomeric fibers. Spandex, produced as continuous-filament yarn, is used almost exclusively to manufacture elastic textiles and is always employed in combination with other fibers. Although spandex has gained considerable technical and economic importance, worldwide production, which amounted to 23 000 t in 1985, is relatively small compared to other textile fibers. Commercial products (see Table 10) have distinctive raw materials bases, chemical structures, and manufacturing and spinning processes, which, in the final analysis, are responsible for the specific balance of properties [126][127][128][129][130].

3.1. Physical Properties

Spandex is highly extensible by application of an external force. When the load is removed,

* TDI, toluene diisocyanate; MDI, 4,4′-methylenebis(phenyl isocyanate).

the material rapidly and completely reverts to its original state. This is a result of the two-phase structure of the hard and soft segments. The soft segments, which are highly mobile at the use temperature, are coiled in the unloaded state and stretched in the loaded state. The restoring force results from the increase in entropy during reversion to the coiled state (entropy elasticity). The crystalline hard segments of symmetrical aromatic urea groups form a network structure via hydrogen bonds and thus provide form stability [131–144].

Characteristic stress – strain curves of a commercial spandex are shown in Figure 14 in a cyclical loading – unloading experiment (stress – strain cycle). The mechanical properties of spandex filament yarns for the usual range of types and finenesses are listed in Table 11 (see → Fibers, 1. Survey, Chap. 5.).

Table 11. Mechanical properties of continuous filament spandex yarns

Property	Range of values
Fineness	20 – 5000 dtex
Elongation at maximum tensile load	
Standard-elongation types	420 – 570 %
High-elongation types	600 – 800 %
Tenacity	
Referred to original fineness	0.45 – 1.2 cN/dtex
Referred to fineness at break [a]	3 – 7 cN/dtex
Cyclic loading to 300 % elongation

∗ 1 is first curve; 5 is fifth curve; –▷– is elongation; –◁– is recovery.

Below the glass transition temperature of the soft segments, spandex loses its elasticity. In commercial products, this temperature of 210 – 250 K is far below normal environmental temperature range. Critically important for textile processors is the behavior at high temperature (160 – 170 °C, which is the temperature during textile treatment and shaping processes).

3.2. Chemical Properties

Compared to rubber yarns, spandex is substantially more stable to chemical influences during textile processing and subsequent use. Any possible damage manifests itself primarily in a loss of strength and an onset of yellowing. As expected, polyether spandex is more affected by oxidative processes and polyester spandex by hydrolysis. The stability of spandex subjected to various chemical treatments is given in Table 12.

Spandex-containing textiles can be cleaned chemically without problem. Sensitivity to photo oxidative damage is increased by unsaturated fatty acids and cosmetic oils [146]. Nitrogen oxides lead to yellowing and, hence, are detrimental to white textiles that contain spandex. Compared to rubber yarns, spandex has a greater affinity for textile dyes.

3.3. Raw Materials

Segmented polyurethane, the raw material for spandex fibers, consists of long-chain dihydroxy compounds (macrodiols), aromatic diisocyanate compounds, and short-chain diamino or dihydroxy compounds (chain extenders). Because of their chain mobility, the long-chain diols (soft segments) are responsible for the extensibility. The urethane and urea groups, formed by aromatic diisocyanates and short-chain diols (hard segments), function as physical cross-links and are the source of yarn strength.

Macrodiols. Macrodiols suitable for the manufacture of spandex have molar masses of 1 – 3 kg/mol and melting points < 50 °C. Only polyether and polyester diol are important. The most frequently used polyether diols is poly(tetramethylene ether glycol) [*25190-06-1*], polymerized from tetrahydrofuran via ring opening (→ Polyoxyalkylenes, → Polyoxymethylenes). Spandex fibers with polyether soft segments are highly resistant to hydrolysis and alkali, and have excellent low-temperature properties. They are, however, sensitive to light, atmospheric oxygen, and the chlorinated water of swimming pools and must be specially protected from them.

Among the polyester diols used, adipic acid polyesters have gained great importance, whereas polycaprolactone diols have not. For polyadipates, mixtures of $C_2 - C_6$ diols, e.g., 1,2-ethanediol – 2,4-butanediol and 1,6-hexanediol – 2,2-dimethyl-1,3-propanediol are used most frequently. Polyester spandex is more resistant to chlorinated water than polyether types and is insensitive to oxidative damage. Its sensitivity to hydrolysis can be reduced by the use of diols with a greater number of carbon atoms. Polyesters of mixed diols give spandex with a low tendency to crystallize during extension and with improved elastic properties.

Trade names. Polyethers: Terathane (Du Pont), Polymeg (Quaker Oats), Poly-THF (BASF), PTMG (Mitsubishi).

Polyesters: Niax (Union Carbide, Desmophen (Bayer).

Diisocyanates. Commercial spandex is almost exclusively produced from 4,4′-methy-

[a] In the classification used, the following strength loss is to be expected: none, 0–5 %; low, 5–20 %; medium, 20–40 %; high, 40–90 %; total, 90–100 %.
[b] Can largely be prevented by use of ZnO as spinning additive [145].
[c] Light source: Hanau 450 (UV-emitting xenon gas lamp).

lenebis(phenyl isocyanate) [*101-68-8*] (MDI; → Isocyanates, Organic). Toluene diisocyanate [*26471-62-5*] (TDI), which was used in the early years of spandex production, is rarely employed today. Although aliphatic diisocyanates lead to polyurethanes with increased light durability, they are of little use because of increased difficulties in processing the spinning solutions. However, 1,6-diisocyanatohexane can be employed as a modifier [147].

Chain Extenders. Most spandex producers use short-chain aliphatic diamines, such as 1,2-diaminoethane or 1,2-diaminopropane, as chain extenders because they give fibers with the best thermal and hydrothermal properties. Hydrazine hydrate, carbonic acid, dicarboxylic acid dihydrazides, aminocarboxylic acid hydrazides, and semicarbazidocarboxylic acid hydrazides [148], [149] were used earlier as chain extenders, but are no longer of any significance. Occasionally, small amounts of codiamines, such as 1,3-diaminocyclohexane [150] or *N*-methylbis (3-aminopropyl)amine [151], are used in combination with ethylenediamine. This favorably affects certain properties, e.g., solubility and storage behavior. 1,4-Butanediol, frequently used in thermoplastic polyurethanes, results in spandex with unsatisfactory properties. 1,4-Bis(2-hydroxyethoxy)benzene, on the other hand, produces a melt-spun spandex with improved properties [152].

Solvents. Spandex fibers based on polyurethane–polyurea decompose during melting; therefore, they are spun from solution. Only dipolar aprotic solvents, usually dimethylacetamide and dimethylformamide, can be used.

Stabiliziers and Adjuvants. Because of the use of aromatic diisocyanates, light tends to discolor spandex [153]. Spandex in which polyethers are used as soft segment is, in addition, attacked photooxidatively. The following are used as stabilizers for these processes: phenolic antioxidants, sterically hindered amines, light-protective agents (e.g., benzotriazoles), and phosphites. They must meet special requirements such as low thermal volatility and good laundering resistance.

Spandex yellows under the influence of nitrogen oxides, which are contained primarily in combustion gases. Tertiary amine compounds have proved to be effective protectors against these; in addition, the patent literature describes a whole series of protective agents, e.g., carboxylic acid hydrazides [154], esters [155], [156], and phosphites [157], [158].

Polyether spandex, which is sensitive to chlorinated water, can be protected by tertiary amine compounds; polymers or polyurethanes with basic groups are used, such as poly(*N,N*-dialkylamino)ethyl acrylates and methacrylates [150], [159]. Protective action is also obtained by inclusion of zinc oxide during spinning [145].

The dyeability of mixed articles (fabrics containing a mixture of yarns of polyamide and spandex) with acid dyes can be improved by adding basic compounds to the spandex. Alternatively, basic substituents, e.g., *N*-alkyldialkanolamines or *N*-alkyldiaminoalkylamines, can be built into the polymer

molecule [160]. Previously, spandex was produced mainly as delustered yarns. Titanium dioxide was used as a delusterant, usually in concentrations of 2 – 5 %, to obtain as good a degree of whiteness as possible. Additional improvement in whiteness was obtained by adding nuancing dyes or pigments. However, nondelustered spandex types have gained greater prominence because they make possible more brilliant colors in dyed polyamide – spandex fabrics [161].

Freshly spun spandex yarn is slightly tacky. After being wound on the bobbin, cohesion between yarn layers develops with storage time. To counteract this and to improve the unwinding and processing behavior, separating and lubricating agents are used, e.g., polydimethylsiloxane and metal soaps [162].

3.4. Production of Polymer

The fiber raw material is produced by the two-stage prepolymer – chain extender process, frequently used in polyurethane chemistry.

Production of Isocyanate Prepolymer. In this process step, an α, ω-OH functional polymer (macrodiol) is reacted with an aromatic diisocyanate (called a polymer-analogous reaction) to yield an α, ω-NCO functional polymer (macrodiisocyanate). The reaction is carried out in the melt or in a highly polar solvent (e.g., dimethylacetamide) at 50 – 80 °C in a batchwise or a continuous process. The molecular mass of the prepolymer, which subsequently plays an important role in determining the elastic properties of the spandex, can be adjusted via the molecular mass of the macrodiol and the molar ratio of NCO : OH [163]. The prepolymers have number-average molar masses of 4 – 8 kg/mol, as well as NCO contents of 2 – 4 wt %, and are generally processed immediately without intermediate storage.

Chain Extension (Polymerization). In chain extension, the macrodiisocyanate is reacted with a diamine in a highly polar solvent (e.g., dimethyl acetamide) to give a high molecular mass polyurethane – polyurea. The most frequently used short-chain aliphatic diamines react rapidly. To obtain a good polymer structure, rapid and intense mixing is, therefore, required during chain extension. Reactivity can be reduced by formation of a carbamate from the diamine and carbon dioxide prior to chain extension [164].

Both batchwise and continuous processes are used during chain extension. Spandex solutions with solids contents of ca. 20 – 35 % and viscosities of ca. 50 – 300 Pa · s (25 °C) are obtained. Molecular mass is controlled during chain extension by using monoamines, e.g., diethylamine, as chain terminators. The polyurethane – ureas produced from diamines are linear polymers and, hence, soluble in the reaction media used.

With trifunctional starting components, covalently cross-linked polyurethanes are obtained, which are simultaneously chain extended and formed into a yarn [149] in the reaction-spinning process (see Section 3.5).

3.5. Spinning Processes

In contrast to elastic yarns based on rubber, spandex can be spun by using technologies generally known in the synthetic fiber industry. Because spandex based on polyurethane cannot be processed thermoplastically, solution-spinning processes are used to produce yarns.

Solution Spinning. Of the solution-spinning processes (dry, wet, and reaction spinning), dry spinning has become the most important because it lends itself more readily than the others to production of the fine spandex yarns that are increasingly in demand today.

Dry-Spinning Process (see Fig. 15). The high-viscosity elastomer solution is spun through multihole spinnerets (d) into heated spinning cells (e). During the process, the solvent evaporates, is absorbed by the entrained hot spin gases (air or inert gas), and is carried away. The solvent is separated by condensation and possibly scrubbing of the off-gas, distilled, and recycled. The individual filaments are cemented with the aid of a false-twisting device (j) to form a multifilament [165], [166]. Finish is applied to the yarn, which is wound up at a rate of 200 – 800 m/min. The drawoff speed is greater than the spinning speed (spin draw). The orientation thus produced affects yarn properties. To improve productivity, several multifilaments are spun from a single

spinning cell at the same time. Figure 16 shows a cross section of a dry-spun spandex yarn.

Figure 16. Dorlastan fiber cross sections, 160 dtex (12 individual capillaries) ∗
∗ ca. 50 µm.

Wet-Spinning Process (see Fig. 17). In the wet-spinning process, the elastomer solution is spun into aqueous precipitation baths (d). In the process, the water-insoluble polyurethane coagulates, and the spinning solvent is carried off by the water. As in dry spinning, the individual filaments are cemented to a multifilament. After the filament has passed through wash baths and drying cabinets, finish is applied and the filament is wound. Windup speeds are significantly lower than in dry spinning, but equipment and energy costs are lower.

Figure 17. Schematic of a spandex wet- or reaction-spinning machine [126]
a) Spinning solution or prepolymer; b) Spinning pump; c) Filter; d) Precipitating or reaction spin bath; e) Spinneret; f) Wash or subsequent reaction bath; g) Finish; h) Windup

Reaction-Spinning Process. In this process, chain extension of the isocyanate prepolymer by the amine and formation of the yarn occur simultaneously in the precipitation bath [167]. During spinning of the prepolymer into the reaction spin bath, a solid polymer skin forms immediately on the yarn surface and provides the stability necessary to draw off the yarn. Complete solidification is achieved in a second step. With this process, producing chemically cross-linked spandex by using trifunctional starting materials is also possible.

Melt-Spinning Process. Only elastic yarns that are exclusively based on pure polyurethane can be prepared by the high-productivity melt-spinning process. These materials do not have the properties of commercial spandex based on polyurea – polyurethane and are, therefore, of little technical significance

3.6. Uses

Production of Elastic Yarns and Fabrics. Spandex fibers are processed and used exclusively in combination with hard fibers to impart high elasticity to textiles. In most cases, the spandex is used in bare form (i.e., unwrapped). Because of its rubberlike hand and poor frictional properties, spandex intended for certain end uses, such as woven elastic clothing fabrics [168], support stockings, and socks, is wrapped or corespun with hard fibers. Of these elastic combination yarns [168], wrapped yarns are the most important. Wrapping can be carried out with one or two textile yarns. Corespun

yarns are produced on special secondary spinning machines on which staple fibers are twisted around the stretched spandex yarn. Corespun yarns are distinguished by a remarkably soft hand. To improve the processibility of the combination yarns, they can be changed by a combined stretch – steam process so that they (temporarily) lose their elastic extensibility. After being processed into fabric, the good elastic properties are restored by dyeing at the boil in the relaxed state.

The most important types of processing used to produce articles containing spandex are listed in Table 13. As can be seen, both knit (processing on circular or warp knitting machines) and woven fabrics can be produced. Articles with the highest extensibility can be prepared by the circular knitting process [169]. The elastic yarn is processed directly from the bobbin, the yarn being taken off over the end of the spool.

To prepare warp knitwear, the elastic yarns must first be assembled [170]. To do so, up to 1500 yarns are wound parallel, side by side, under constant extension onto a warp beam. Here, processing is exclusively in the bare form. By varying the fineness, the hard fiber yarn, and the pattern notation technique, the properties and appearance of the articles can be influenced in many ways with this process and can be adapted to both functional requirements and the demands of fashion [171], [172].

Processing of elastic yarns in woven fabrics has increased substantially. End uses are suit-coat and pants fabrics for articles with increased wear comfort.

The major end uses for coarser spandex yarns and elastic wrapping yarns are tapes for various textile and engineering applications. In Western Europe, 45 % of spandex production is used in girdle and underwear manufacture, 20 % each in swim wear and hosiery, and ca. 15 % in other areas.

Textile Properties of Elastic Fabrics. The most important property of elastic fabrics is the combination of extensibility and elastic recovery. Spandex can elongate until the hard fiber construction obstructs further elongation. Extensibilities vary from ca. 25 % (woven fabrics) to > 200 % (knitwear). The elastic behavior of a warp-knitted fabric is shown in Figure 18.

Figure 18. Curves of cyclic elongation of a tricot fabric (longitudinal direction) containing 18.5 % 45-dtex Dorlastan, unit mass 220 g/m^2, longitudinal extensibility 210 % ∗ [126]
∗ 1 is first curve; 5 is fifth curve; –▷– is elongation; –◁– is recovery.

By using spandex, the textile industry can fabricate elastic textiles in great variety, having given shaping and support forces, and also meeting all requirements with respect to end-use behavior, comfort, and fashion.

4. Polyolefin Fibers

Polyolefin fibers, yarns, and monofilaments are usually produced by melt spinning. Film yarns and split yarns, obtained from films by uniaxial stretching, are also produced in large quantities. Polypropylene (PP) is the predominant raw material for fibers and yarns. High-modulus yarns of ultrahigh molecular mass high-density polyethylene (HDPE), commercialized in the mid 1980s, are an exception.

Both PP and HDPE are used to make film yarns and monofilaments; however, HDPE is used to a much lesser extent. Areas of application for PP fibers include carpet yarns, home furnishing fabrics, industrial fabrics, and nonwovens. Polyolefin tapes and monofilaments are used in bags, tarpaulin, industrial fabrics, carpet backing, twine, rope, and bristles.

The production of textile products from polyolefins in 1985 was estimated to be ca. 1.7×10^6 t, about 91 % (1.55×10^6 t) of which was PP and

Table 13. End uses of spandex continuous-filament yarns

End use	Manufacturing technology	Amount of spandex, wt %	Yarn type	Fineness, density, dtex
Lingerie and lingerie bands	circular knit	5 – 12	bare, wrapped, corespun	22 – 400
	warp knit		bare, wrapped	22 – 80
Girdles	warp knit	10 – 40	bare, wrapped	22 – 800
Swim wear	warp knit	10 – 32	bare,	22 – 80
	circular knit	6 – 12	bare, wrapped	44 – 160
Hosiery bands, sock borders	circular knit	10 – 20	bare, wrapped	135 – 400
Support stockings	circular knit	10 – 60	bare, wrapped, corespun	22 – 480
Tapes	tape weaving	10 – 50	bare, wrapped	320 – 5000
Outerwear	weaving	2 – 10	rubber threads, wrapped yarns	44 – 160

about 9 % (150 000 t) HDPE. About 30 % of all polypropylene produced is processed into tapes, fibers, and monofilaments. In 1985, this amounted to ca. 630 000 t in Western Europe, 47 % of which went into tapes, split fibers, and monofilaments; 32 %, into staple fibers; 13 % into filament yarns, and 8 % into spunbonds. The growth of polypropylene yarns, fibers, and nonwovens should continue to be above the growth of polypropylene consumption in general as well as that of all other synthetic fibers.

4.1. Polypropylene Fiber

Polypropylene fiber was developed in Italy by Montecatini during the second half of the 1950s [173]. Several other companies initially played an active role in its development, including Hercules, Reeves Brothers, Vectra, and Phillips in the United States; ICI in Europe; and Toray, Mitsubishi Rayon, and Toyobo in Japan. Some of them, like ICI, disappeared from the scene after the first few years; others improved their line of products and became extremely important in the market. There are many producers; in Western Europe they increased in number during the late 1970s, when the Montecatini patents expired.

4.1.1. Chemical and Physical Properties

Chemical Structure. Polypropylene is a hydrocarbon made up of $-CH_2CH(CH_3)-$ units. These propylene units form a stereoregular helix, with the methyl groups at an angular distance of 120° (isotactic polypropylene). A small percentage (ca. 2.5 – 5 %) is sterically random (atactic polypropylene).

Because its structure contains no polar groups, PP is resistant to most chemical agents, in particular to acids and alkalies; insensitive to water; and not dyeable with common types of dyes. Moreover, it has a low resistance to thermooxidative and photooxidative degradation. The problem of nondyeability has been solved by mass dyeing techniques (Section 4.1.2.5) and the problem of degradation by the use of suitable additives (Section 4.1.2.4). Because of the absence of polar groups, only van der Waals forces exist between macromolecules; these forces are much weaker than the hydrogen bonds found, for example, in polyamide. Because mechanical characteristics depend on these forces and on molecular entanglement, very high molecular masses (M_r from ca. 170 000 to 300 000, compared to ca. 20 000 for polyamide) must be used to obtain satisfactory strength (fiber tenacity).

Rheological Aspects [174]. Polypropylene fiber is produced by melt spinning, i.e., by extruding the molten polymer through suitable spinnerets. Therefore, the rheological behavior of the polymer melt must be considered in selecting processing conditions or even in choosing a certain polymer for specific spinning conditions. The first aspect to be considered is that isotactic PP in the molten state is highly non-Newtonian and exhibits a strong pseudoplastic character; the apparent viscosity of the melt is not constant with varying shear stress but it decreases when shear stress increases. The deviation from Newtonian behavior is markedly dependent on the relative molecular mass (M_r) and polydispersity (molecular mass distribution M_rD); for polymers of comparable polydispersity, the melt

viscosity increases with increasing viscosity–average molecular mass. An extremely useful, practical indication of M_r is the melt flow index (MFI), which is a measure of flow under standard conditions (ASTM D 1238: grams extruded in 10 min through a standard orifice under a pressure of 2.16 kg/cm^2 at 230 °C); MFI is inversely proportional to melt viscosity. The MFI is measured at a shear rate close to those commonly met in usual spinning processes.

The initial MFI of PP polymers used in fiber production ranges from 2 to 35, depending on the process involved and the type of fiber produced. In addition to pseudoplasticity, PP melt exhibits appreciable signs of viscoelasticity. In a viscoelastic material the deformations undergone by the melt have not only a viscous but also an elastic component, which can therefore be recovered when the applied stress ceases, i.e., when the extruded polymer emerges from the spinneret capillary. The residual elastic energy, whose magnitude depends on the residence time in the capillary, can cause, among other phenomena, enlargement of the extrudate to a diameter larger than that of the capillary (die swell). The polymer swelling increases as the shear stress increases and as the ratio of length to capillary radius decreases.

Die swell also depends on the molecular mass distribution (M_rD): at comparable melt viscosities, die swell is larger for a polymer with broad M_rD than for a polymer with a narrow M_rD. Swelling increases as temperature decreases. All these rheological characteristics are taken into account when spinneret hole geometry, polymer type (MFI, M_rD), and extrusion conditions are being selected.

Structural Characteristics [174, pp. 327–337], [175]. The stereoregular structure of isotactic PP macromolecules makes an ordered three-dimensional configuration (i.e., a crystalline structure) possible when the molten polymer is cooled to the solid state. Under normal conditions, isotactic PP crystallizes in the monoclinic system; if cooled rapidly to room temperature, it exhibits a paracrystalline form, called smectic. In practice, PP fiber is a partially crystalline material. The crystalline structure of the fiber depends on the conditions of extrusion and quenching, the take-up speed in the spinning step, and the draw ratio and annealing conditions in the finishing step. Normally, the crystallinity of the finished fiber does not exceed 70 %; values of 40–50 % are usual. Many physical properties are influenced by crystallinity. Mechanical properties, however, are affected less by the percentage of monoclinic material than by the molecular orientation imparted during drawing; orientation is evaluated by measurement of birefringence.

Mechanical Properties. Depending on spinning conditions (extrusion temperature, quenching, spinning speed, and rate of deformaton in the molten state), the mechanical properties of as-spun PP fibers can vary widely, as shown schematically in Figure 19. The mechanical properties of drawn fibers are influenced substantially by the applied draw ratio and, consequently, also vary widely (Fig. 20).

Figure 19. Stress–strain curves of as-spun polypropylene fibers

Figure 20. Stress–strain curves of drawn polypropylene fibers

The relationship between tenacity and draw ratio depends on the polymer used and, in particular, its polydispersity. As polydispersity decreases, the tenacity obtained at a given draw ratio increases, but the drawability of the spun fiber decreases at the same time. Therefore, polymers with narrow M_rD are not suitable for production of high-tenacity fibers; they do, however, have advantage in terms of spinning continuity at high spinning speeds.

4.1.2. Production

4.1.2.1. Raw Materials

Polypropylene fibers are obtained from PP homopolymer. They may also be based on PP and a propylene – ethylene random copolymer or a blend of polypropylene and polyethylene homopolymers. In the latter case, the definition "polyolefin fiber" or "olefin fiber" is more correct (see Section 4.2). However, polyolefin is also frequently used for PP homopolymer fiber.

Polypropylene is used in the production of side-by-side bicomponent polypropylene – polyethylene fibers. The Customs Cooperation Council of the European Economic Community (EEC) adopted the following definition of textile polypropylene:

Fibers composed of aliphatic saturated hydrocarbon linear macromolecules having in the chain at least 85 % by weight of units with one carbon atom in two carrying a methyl side chain in an isotactic position, and without further substitution.

Availability. The availability of raw materials is not a problem, although the supply of propylene may be influenced by the demand for ethylene because ethylene and propylene are coproducts in the cracking of virgin naphtha. Other sources, of lesser importance at the moment, are liquefied refinery gases containing propylene and propane gases.

4.1.2.2. Staple Fiber Production Process

Polypropylene can be produced by two different processes: (1) *conventional spinning* is based on high spinning speeds and spinnerets with a rather limited number of holes; (2) *short spinning* is based on low spinning speeds and spinnerets with a large number of holes. In the first process, because of the high spinning speeds, postspinning operations are performed in a separate step; in the second process, because of the low spinning speeds, spinning and postspinning are carried out continuously. Postspinning operations are basically the same for both processes.

Conventional Spinning Process. The polymer, to which stabilizers and pigments have been added, is introduced into the extruder (a) (Fig. 21). The molten material is fed to the spinnerets (e) by metering pumps (c), which control the throughput of each spinneret. The extruder is heated electrically, while the melt distribution manifold is heated by means of a diathermic fluid (e.g., Dowtherm and Diphil). Filaments (f) emerging from the spinneret are quenched with cold air (air speed 1 – 2 m/s) and, when solidified, collected in cans (i). An antistatic and lubricating agent is usually applied to the filaments before they come in contact with any solid surface (g).

The filament fineness depends on the throughput of the metering pump, the number of holes in the spinneret, and the take-up speed, according to the following relationship:

$$d = \frac{1000}{3.6}\,\frac{Q}{n \cdot v}$$

where d is the fineness, decitex; Q is the pump throughput, kilograms per hour; n is the number of holes; and v is the take-up speed, meters per second. The spinning speed of PP fiber is usually 600 – 1200 m/min, and the temperature of the molten polymer in the spinneret is 220 – 300 °C, depending on molecular mass of the polymer, spinning speed, and desired characteristics of the fiber being produced. Spinnerets used for staple production are 150 – 250 mm in diameter and have between 200 and 2000 holes, depending on the fineness of the fiber. In some cases, rectangular spinnerets are used to achieve higher productivity. The number of holes is limited to avoid having the filaments stick together (filament marriage). Polymers with a fairly low M_r (MFI 5 – 20) are used commonly in the production of standard fibers; higher M_r (MFI ca. 2) polymers are used only for high-tenacity fibers. To obtain satisfactory spinning continuity, the

Figure 21. Conventional spinning plant

polymer must be filtered before reaching the spinneret; both sand filters and screen filters are used.

Postspinning Operations. Drawing, crimping, heat setting, cutting, and baling are the steps that follow spinning in the production process.

Several tows coming from the spinning section are processed together to reach a total fineness of 200 – 300 ktex (0.2 – 0.3 kg/m). They are stretched between two sets of rolls; the draw ratio depends on the ratio of the roll speeds of these two sets. The draw ratio for standard fibers is between 1 : 3 and 1 : 5. To obtain uniformly drawn fibers, the tow is heated in a steam chamber located between the two sets of rolls. Alternatively, heated rolls can be used in the first set. If high-tenacity fibers are desired, the drawing operation is sometimes divided into two steps by means of a third set of rolls. Crimping is intended to impart bulk and cohesion to the fiber for subsequent conversion to final products. The fiber is compressed in the crimper (stuffer box) and subsequently dried and heat-set in a hot-air oven (100 – 130 °C) to stabilize crimp and reduce thermal shrinkage after drawing. A finish is usually applied to the fiber during the postspinning operations. Staple cutting and baling operations are the final stages of production. The speed of these operations is limited by the crimping speed and is generally 150 – 250 m/min.

Short Spinning Process. The rheological behavior of PP is such that, when spinning speeds are fairly low ($\leq$ 120 m/min), and the stream of quenching air blows through the filaments close to the spinneret, the filaments do not stick together even with close hole spacing (ca. 1 mm). Then, the speed of consecutive operations can be matched, and a continuous,

uninterrupted, one-step process can be achieved. A consequence of the high hole density and the reduction in height of the quenching section is that plants can be made more compact for a lower cost. For this reason and reduced manpower requirements, the short spinning process has become very popular.

Figure 22. Draw-twisting machine
a) Spun yarn; b) Pre-tension guide; c) Pre-tension rolls and guides; d) Feed roll; e) Draw roll; f) Twisting take-up

4.1.2.3. Continuous Filament Yarn Production Process

In principle, spinning continuous filament yarn is similar to spinning staple fiber; the main difference is that in the former, each yarn is collected on an individual bobbin. Drawing of the yarn (Fig. 22) is usually performed by two pairs of rolls (f), which are generally heated electrically. For some applications, continuous filament is used as it comes from the drawing machine (flat yarn), but in most cases, filament bulk must be increased by means of a texturing system. A mechanical texturing system is preferred for the very fine yarns used in the textile industry. In this case, the yarn is highly twisted, heat-set, and detwisted in a continuous false-twisting process to give each individual filament the shape of a spring. A subsequent heat-setting operation can be introduced in the detwisting zone to reduce yarn elasticity. For coarser continuous filament yarns (carpet yarns), systems based on fluid bulking jets are used. Consistent with the continuing trend toward reduced production costs, machines have been developed in which the different operations are performed continuously in a single step.

4.1.2.4. Stabilization

Polypropylene, although relatively stable to heat and light in the absence of oxygen, has poor resistance to thermooxidative and photooxidative degradation [175, pp. 38 – 93]. Thermooxidative degradation occurs during conversion of the polymer to a fiber. Photooxidative degradation occurs when the end product, which contains PP fiber, is exposed to direct or diffuse solar radiation in the presence of oxygen. As a hydrocarbon, PP is transparent to UV light but it is sensitive to it because of the presence of traces of oxygen-containing groups, such as hydroperoxides and ketones, which absorb at 310 – 330 nm. Depending on the temperature during exposure, thermooxidative degradation and photooxidative degradation often occur simultaneously. Both processes generate polymer radicals, which catalyze further molecular cleavage.

Therefore, suitable antioxidants and light stabilizers are added to protect the polymer melt at high temperature and to impart sufficient aging resistance to the finished products. (→ Antioxidants, Chap. 5.4.). These stabilizers can be classified according to the mechanism by which they protect the polymer: (1) chain terminators or free-radical scavengers, which terminate the chain reaction by giving rise to nonreactive radicals; (2) hydroperoxide deactivators, which decompose hydroperoxides without formation of radicals; (3) UV absorbers, which screen UV radiation; and (4) quenchers, which quench the excited states of ketone groups; and (5) free-radical scavengers that trap the radicals and regenerate themselves (HALS: hindered amine light stabilizers). The following are some of the chemicals used at present:

Chain terminators	phenolic antioxidants
Peroxide decomposers	disulfides, trialkyl phosphites
UV absorbers	derivatives of hydroxybenzophenone and benzotriazole
Energy quenchers	nickel chelate stabilizers
Free-radical scavengers	hindered amines [176]

Some producers of stabilizers are:

Ciba-Geigy	B. F. Goodrich Co.
Borg Warner Chemicals	Enichem
Uniroyal	Ethyl Co.

The effectiveness of the stabilizer formulation depends on the choice of individual components. This choice must also take into account the pigments used because they can affect heat and light stability significantly and can even interfere with stabilizers. In addition, attention must be paid to possible concomitant phenomena, such as gas fading, which is the color change caused by nitrogen oxides present in air. These oxides can react with some components of the stabilizing system, resulting in nitration of aromatic rings or addition of nitrogen oxides to double bonds. Nitrogen oxides can also react with certain finishes and cause color changes via some of the reactions mentioned previously.

The stabilizer formulation also includes antacids, typically calcium stearate, which react with the HCl formed by reaction of catalyst residue with substances containing active hydrogen. Stabilizer systems that comply with international regulations for chemicals in food contact applications are also available.

Stabilizer Evaluation. The following test methods have been developed to select the most suitable stabilizers and predict actual fiber behavior.

Oxidation Resistance. Fiber bundles, hung on a rotating frame under a small weight, are exposed in a forced-draft oven at 110 °C. Resistance to oven aging is expressed as days to failure. For operating conditions, see ASTM D 3045-74 (reapproved 1979).

Light Resistance. Accelerated tests with instruments based on a xenon lamp are preferred to those using a carbon-arc apparatus because the xenon lamp gives a spectrum similar to that of summer sunlight, whereas the carbon-arc apparatus is too high in UV radiation. Exposure conditions are selected so that the temperature is comparable to that experienced in use because the rate of photooxidation is a function of temperature. For indoor uses, such as carpets and wall coverings, fiber bundles are exposed in a Xenotest or Weatherometer according to ASTM G 26 – 84, DIN 54 004, ISO B 02. The resistance to artificial light is expressed as residual tenacity after exposure. Fiber exposed to combined heat and light, e.g., on rear window shelves in cars, is tested in the Xenotest at high temperature.

Gas-Fading Resistance. The fiber specimen is exposed to nitrogen oxide containing gases derived from the combustion of butane. Color variation is assessed by comparing the exposed and original samples after four exposure cycles of controlled duration.

4.1.2.5. Pigmentation

Polypropylene cannot be dyed by conventional methods because it lacks polar groups that can provide suitable sites for dyes. The techniques proposed thus far for making PP dyeable by traditional acid or disperse dye systems do not have near- or medium-term commercial potential, either because of the relatively high cost of additives involved or because of the as yet insufficient colorfastness. Only nickel-modified fibers are used commercially for space dyeing or printing.

For these reasons, PP fiber is colored by blending the polymer with suitable pigments prior to extrusion; this system is known as "melt dyeing" or "mass dyeing." Because of various requirements, such as thermal stability at high temperature, the range of pigments that can be used is limited; however, mass-dyed PP fibers are characterized by high colorfastness to light, heat, rubbing, and washing. Colorfastness may, of course, be affected by stabilizer – pigment interaction or by additives that facilitate extraction of the pigments. The main classes of pigments used are the following:

Inorganic:	titanium dioxide (rutile or anatase)
	iron oxides
Organic:	insoluble azo pigments
	copper phthalocyanines
	vat pigments
	carbazole dioxyazine
	carbon black

Some pigment producers are:

BASF	Bayer
Sandoz	Farbwerke Hoechst
Ciba-Geigy	Cabot

4.1.3. Uses

Types of Fibers Produced. Polypropylene fiber is produced in a wide range of finenesses, both as staple and continuous filament. Staple fibers range from ca. 1 to 250 dtex per filament. The fiber cross section is primarily circular; the fineness range of continuous-filament yarn is 70 – 12 000 dtex. The filament cross section is predominantly circular in the low to medium fineness for apparel, upholstery, and industrial uses, and triangular or trilobal for the fibers used in floor covering. For the latter application, the basic fineness range is 1300 – 4000 dtex; higher fineness up to 12 000 dtex is obtained by comingling.

Commercial Mass. The International Bureau for the Standardization of Man-Made Fibers (BISFA) has agreed on the following definition of commercial mass: "the commercial mass shall be obtained by adding to the oven-dry mass, i.e., after removal of finish, etc., the mass corresponding to the conventional allowance" where "the conventional allowance for polypropylene staple fiber, sliver or top and tow is 2.0 %."

Properties and Applications. Polypropylene fiber has physical, chemical, and mechanical properties that make it suitable for a wide range of applications. These properties can be divided into the following groups:

Good
Relative density
Resistance to acid and alkali
Abrasion resistance
Moisture absorption
Mechanical properties under dry and wet conditons
Dimensional stability
Stain and soil removal
Easy washing
Quick drying
Static buildup in carpets
Resistance to mildew, microorganisms, and insects
Thermal bondability
Colorfastness of suitably pigmented fibers
Light resistance of suitably stabilized fibers

Fair
Flammability
Frictional characteristics
Oil-based soil removal

Poor
Dyeability with common dyeing methods (need for pigmentation)
Heat and light resistance (need for stabilization)
Resistance to dry-cleaning solvents
Behavior during ironing

Some properties are inherent in the component material; others are imparted or enhanced by the production process or by suitable additives. A brief survey of the major properties follows, with an indication of their effect on fiber application.

Relative density (0.91) is the lowest of all commercial textile fibers; this is an advantage in all applications because it means lightness and high cover (especially in nonwoven construction).

Chemical resistance, especially to acid and alkali, is outstanding. Polypropylene fiber was treated at 20 °C with the following chemicals; the residual tenacity after 96 h is given (in percent):

Nitric acid (66 %)	80 – 87
Sulfuric acid (95 %)	95 – 100
Formic acid (75 %)	100
Sodium hydroxide (40 %)	100
Concentrated aqueous ammonia	95 – 100
Trichloroethylene	80
Perchloroethylene	80
Xylene	80
Toluene	90
Benzene	90
Acetone	100
Sodium hypochlorite (5 % active chlorine)	85
Hydrogen peroxide (12 parts)	90

Hot halogenated solvents swell PP fiber, with subsequent shrinkage on drying (trichloroethylene), or even dissolve it (boiling perchloroethylene). Moreover, some boiling aromatic solvents dissolve the fiber (e.g., xylene, decahydronaphthalene), and strong oxidizing agents attack it. In the last case, however, the fiber can be improved

considerably by suitable stabilizer formulations. The high chemical resistance is exploited in industrial filtration.

Abrasion resistance is comparable to polyamide. It increases with increasing crystallinity and molecular mass and is influenced by frictional properties. The high abrasion resistance is exploited in floor covering, upholstery, hosiery, and industrial applications.

Moisture regain is virtually nil (0.05 % at 65 % R.H. and 21 °C). The insensitivity of PP fiber to water brings about the following advantages: dimensional stability, fabric dryness in contact with the skin, quick drying, and no variation in mechanical properties under wet conditions.

Temperature Behavior. Polypropylene fiber does not distort when exposed to temperatures of 120 – 130 °C during conversion processes; however, it is sensitive to pressure at elevated temperature, so ironing can cause the fabric to stiffen. The softening point is 150 °C, and melting occurs at 168 °C. The relatively low melting point is exploited in thermal bonding, which has become important in hygienic and medical applications (calender bonding is generally used, but flow-through bonding with hot air can also be applied). High-temperature tentering treatment is used to produce dense nonwovens suitable as coating substrates.

Dyeability. Because PP fiber is not dyeable by common dyeing methods, pigmentation is used. Although a nickel-modified fiber is available for printing or space dyeing with chelatable dyes, its use is limited. The absence of polar groups in the PP molecule makes for easy stain removal; on the other hand, PP is more easily soiled by oil-based stains than other synthetic fibers.

Resistance to Mildew, Microorganisms, and Insects. Polypropylene fiber is neither attacked by mildew and molds nor damaged by insects.

Static Buildup. Limited charges are separated when a person walks on a PP carpet and, consequently, a low body voltage is generated, lower than that at which uncomfortable shocks can be felt.

Flammability. Application of a flame causes PP to shrink, melt, and burn if contact with the flame is sufficiently prolonged. Polypropylene burns slowly and drips like a candle. Burning can continue even if the flame is withdrawn because the limiting oxygen index of PP is 18.5. The self-ignition temperature is 570 °C.

Frictional Characteristics. The coefficient of friction of PP fiber, both fiber-to-fiber and fiber-to-metal, is fairly high. Suitable lubricants are applied to keep it low so as to allow conversion by textile processing. Cotton spinning is one of the most critical processes.

Electrical Properties. Polypropylene is a good insulator and exhibits an extremely low power loss, even at high frequencies. The dielectric constant is 2.1 at 60 Hz and 2.2 at 1 MHz; the power loss factor is 0.0002 at 60 Hz and 0.0003 at 1 MHz; volume resistivity is 4.9×10^{14} Ω cm.

Thermal Properties. The thermal conductivity of PP fiber is the lowest among commercial fibers (0.138 $W\,m^{-1}\,K^{-1}$). This contributes to high thermal insulation in textiles, although the major contribution comes from air trapped in the structure.

Allergic Phenomena and Nontoxicity. Polypropylene itself does not cause skin irritation or sensitization and is not toxic; surface finishes must be selected correctly to retain these advantages.

Applications. The three major fields of application are in industrial, home textile, and apparel end uses.

Industrial applications include rope, twine, conveyor belts, industrial sewing thread, filter cloth, paper reinforcement, geotextiles, coating substrates, and carpet backing. Diaper facing is an example of a hygienic – medical product in which PP has made rapid inroads.

Home textile applications include floor covering (tufted, woven, and needle punched), upholstery fabric, wall covering, fiberfill, blankets, warp yarns in woven carpets, and yarns for secondary backing for tufted carpets. Floor coverings constitute the most important outlet for PP fiber, in both bulked continuous filament (BCF) and staple.

The *apparel uses* of PP are limited by lack of dyeability, difficulty in ironing, and inability to be dry-cleaned. However, the fiber is established in knitwear, especially sportswear. Staple and textured continuous filament yarns are used. Other applications include fleece fabrics, hosiery, and hand knitting yarns.

4.1.4. Economic Aspects

Cost. Although the price of PP in fiber production may be influenced by the demand for polymer in other areas of application, the price is generally lower than that of other fiber-forming polymers because of the shorter "chemical path" from virgin naphtha from which they are all derived. Another positive aspect is the improvement of bulk polymerization processes based on high-yield catalysts, which reduce production costs considerably.

Production. In 1985, world production of PP fiber was about 650 000 t [177], 250 000 t of which were produced in Western Europe (180 000 t of staple fiber and 70 000 t of continuous-filament yarn). Some producers and *trade names* are listed in Table 14 [178], [179].

Table 14. Trade names of polypropylene fibers

Country	Producer	Trade name *
Austria	Chemie Linz	Asota (ST, Y)
former Czechoslovakia	Chemosvit	Prolen (Y)
Denmark	Danaklon	Danaklon (ST)
		Danaklon ES (ST)
Federal Republic of Germany	Faserwerke Bottrop	Vegon (ST)
	Steen	Polysteen (ST)
Italy	Filatura di Delebio	Delebion (Y)
	Moplefan	Meraklon (ST)
		Meraklon CF (Y)
		Meraklon BCF (Y)
Japan	Chisso	Chisso Polypro
		Chisso ES (ST, Y)
	Daiwabo	Daiwabo Polypro (ST)
	Mitsubishi Rayon	Pylen (Y)
United Kingdom	F. Drake	Gymlene (ST)
	Plasticizers	Charisma, Duron (ST, Y)
United States	Amoco	Marquesa Lana, Propex III (ST, Y)
	Hercules	Herculon
		Herculon Nouvelle (ST, Y)
	Phillips	Marvess (ST, Y)

* ST = staple fiber; Y = continuous filament yarn.

The amount of fiber produced is not commensurate with other synthetic fibers, such as polyester, polyamide, and acrylic fibers, but is, nevertheless, significant and continues to increase steadily. The reason for this steady, though not explosive, increase is not only the interesting performance of the product but also the favorable cost of the raw material and the development of production systems with low investment costs and reduced labor requirements. Another significant factor is the solution of problems regarding stabilization as well as the availability of economical and effective pigmentation methods. Pigmentation has eliminated the basic drawback of the fiber, i.e., its nondyeability.

4.2. Polyolefin Film Yarns and Split Yarns

The production of polyolefin film yarns and split yarns is a relatively recent route to the manufacture of textile products, compared to customary spinning processes that have been in use for a long time. Basically, the process involves production of a primary film, which is subsequently cut, stretched, and possibly fibrillated mechanically. This method had been developed and patented by the end of the 1930s [180] but was not exploited industrially on a broader basis until the 1960s.

In principle, other thermoplastics can also be produced by this means. However, it is important only for polypropylene and for high-density polyethylene (HDPE) (→ Polyolefins).

The usual size of individual PP film ribbons is between 300 and 2500 dtex; split yarns often have sizes up to 10 000 dtex. The smallest size attainable by special processes is ca. 10 dtex.

The literature on PP film yarns and split yarns has been reviewed [181–185].

4.2.1. Raw Materials

The choice of raw materials depends not only on what is required of the finished product but also on the processing properties. Basically, raw materials with higher molecular masses (lower melt flow indices) are used to produce film yarns and monofilaments than to produce melt-spun multifilaments. The choice between PP and HDPE is governed by the following properties:

1) Polypropylene has higher strength, i.e., greater tenacity, than HDPE (see Figure 23) [186], [187]. In addition, PP exhibits less "cold flow"; i.e., products of PP have lower elongation under continuous mechanical loading than those of HDPE.

2) Tapes and monofilaments of HDPE are more flexible than those of PP and give finished products with a softer hand.
3) Polypropylene can withstand a higher thermal load because of its higher melting temperature (≅160 °C vs. ≅130 °C for HDPE).
4) On the other hand, HDPE has better resistance to cold. Although stretching substantially improves the resistance of PP to cold, HDPE is at present preferred for applications below freezing temperature because it offers a greater margin of safety.
5) Tapes and monofilaments of HDPE have lower coefficients of sliding friction than those of PP. Consequently, they are better suited for processes in which good sliding ability is needed (for example, processing on knitting machines).
6) The tendency of HDPE tapes to split is much lower than that of PP. Depending on end use, this can be an advantage or a disadvantage.
7) The UV stability of HDPE is inherently better than that of PP. Nevertheless, very good weathering resistance has now been achieved with PP tapes and monofilaments by using high-efficiency UV stabilizers of the hindered amine light stabilizer (HALS) type.

Figure 23. Tenacity (——) and break elongation (– – – –) of film yarn of polypropylene (PP) and high-density polyethylene (HDPE) as a function of draw ratio [186]

The HDPE types used have densities between 0.945 and 0.960 g/cm^3 and melt flow index values (MFI 190/2.16, i.e., MFI measured at 190 °C under a load of 2.16 kg/cm^2) between 0.3 and 0.7 g/10 min; a broad molecular mass distribution is preferable.

Polypropylene tapes are produced almost exclusively from homopolymers. Depending on the process employed and end uses envisioned, melt flow indices (MFI 230/2.16) between 1.5 and 6 g/10 min, and preferably between 2.5 and 4 g/10 min, are common. If the process involves cooling via a water bath, PP types with low water pickup (carry over) are required.

Coloration is achieved by pigment compounds; to minimize splitting and assist in weaving PP ribbons, inorganic fillers (e.g., chalk) are used.

In special cases, copolymers (i.e., blends with other polymers) or coextrudates can be used to achieve certain properties. Coextruded films permit the production of crimped tapes and yarns [188][189][190].

4.2.2. Production of Tapes and Split Yarns

The stretching process in which the film strips are drawn to many times their original length (in most cases, six to ten times) is the central processing step. It leads to high molecular orientation in the longitudinal direction and to substantial increase in strength with simultaneous decrease in break elongation. However, strength in the transverse direction clearly decreases. At high draw ratios, this effect can cause the tape to "split," i.e., to fibrillate even at low mechanical stress. This phenomenon, which is more pronounced for PP than for HDPE tapes, is undesirable in some cases, e.g., for bagging and packaging fabrics. In other cases, it is exploited and reinforced intentionally (e.g., by profiling the ribbons or by using fibrillators) to arrive at products with lower fineness and more textile-like properties (split yarns and fibers).

Figure 24 is a generalized scheme for the production of film ribbons and split yarns. The processing steps follow.

Production of Film. In general, extruders (a) with screw diameters of 90 or 120 mm and screw lengths $\geq$ 25 times the diameter are used. Screws with a compression ratio of ca. 1 : 3, with a shear and mixing section, have proved useful. Cooled groove boxes in the feed section lead to more uniform granulate feed and higher throughput. In this case, flat cut screws with combined high-efficiency mixing and shearing sections can be used. The type of film production as well as the conditions of cooling and extrusion affect processing and properties of the end product [186], [191], [192]. Tapes of HDPE are usually produced from tubular films (b_1), and

Figure 24. Production of film yarns and split fibers
a) Extruder; b_1) Tubular film (air cooled); b_2) Cast film (water quenched); b_3) Cast film (chill roll quenched); c) Knife beam; d) First godet stand; e) Stretching oven; f) Second godet stand; g) Setting oven; h) Third godet stand; i) Fibrillator (optional, only used for split fiber production); j) Windup; k) Twister; l) Staple cutter

PP tapes preferably from cast films. The cast film can be cooled in a water bath (b_2) at 15 – 40 °C. This type of cooling is particularly effective because it permits high operating speed, leads to the formation of small crystallites, and is advantageous with respect to stretching behavior and strength of the tapes obtained. Raw materials with low water carry over must be chosen, and wiping, suctioning, and squeezing devices must be provided so that no water is entrained in the stretching section or the edge strip return. Film production by the chill roll process (b_3) is used only when exceptionally close thickness tolerance and high tape uniformity are required. Throughput is normally lower in tubular film installations than in cast film units because of lower cooling intensity; in addition, larger variations in film thickness are to be expected.

Cutting. Normally the film is cut prior to stretching. This is accomplished with blades arranged at the desired distance on a knife beam (c). In principle, it is also possible to stretch the whole film and cut it only after stretching and setting. The high splitting tendency of PP makes it difficult to obtain a cut completely free of nicks, so only HDPE is processed this way [193], [194].

Stretching. Stretching is accomplished by guiding the film strips over mechanically driven cantilevered feed rolls. The stretching unit is made up of two sets of godets (d) and (f) usually consisting of seven godets each. The second set runs at a higher speed than the first; the draw ratio is determined by the difference in speeds. Draw ratios from 1 : 6 to 1 : 8 are used to produce tape for weaving and warp knitting; for rope, cable, and twine, draw ratios are ca. 1 : 9 to 1 : 10. Operating speeds are ≤ 300 m/min.

Stretching in the short gap between rolls occurs mainly through reduction in thickness without appreciable loss in width. This leads to some orientation in the transverse direction and, hence, a reduction in splitting tendency. Stretching is generally carried out in hot air ovens (e) or on heated plates.

The overall stretching process is exothermic. However, heat must be supplied to initiate it and to assure uniformity at the high speeds required. The required temperature depends on the raw material, the operating speed, and the desired tape properties; for the most part, it is between 130 and 180 °C. Whereas the temperature of the tape itself cannot be measured, the uniformity of stretching conditions can be checked by measuring yarn tension [195].

Setting. After stretching, setting (g), i.e., controlled shrinkage, is accomplished between the second and third godet stand by again supplying heat (in a hot-air oven or with the aid

of heated rolls). In this annealing process, the orientation stresses introduced during stretching are relieved. In so doing, subsequent undesired and uncontrolled shrinkage is reduced or prevented.

The setting temperature is either equal to the stretching temperature or 10 – 20 °C below it. A higher setting temperature leads to less shrinkage but adversely affects tape strength. Setting shrinkage results from the difference in drawoff speeds between the second and third godet stand. For most applications, adjusting the setting shrinkage to ca. 5 % is sufficient. For end uses in which particularly high dimensional stability is required (e.g., carpet backing), a higher setting shrinkage (10 – 15 %) must be selected.

Splitting and Fibrillating. Polypropylene tape has a relatively high tendency to split, and the propensity for fibrillation increases with increasing degree of stretching. The spontaneous splitting tendency is occasionally exploited in the production of twine and packaging yarns. The tapes split even during twisting (k) and give a fibrous, textilelike end product. The splitting tendency can be reinforced by adding other polymers [196].

Figure 25. Networklike fibrillated yarn of propylene

Fibrillated yarns or fibers with still lower individual fineness and greater softness are obtained by special fibrillation processes. Stretched film strips are generally guided over a needle roll revolving at controlled speed (i); the direction of rotation of the roll coincides with the running direction of the tapes. The tapes are split into a networklike multiplicity of fibrils (Fig. 25). Depending on the number, fineness, and arrangement of the needles, as well as the speed of rotation of the roll, various fibrillar structures can be obtained [196–200].

Strongly fibrillated tape yarn can also be obtained without needle roll from profiled primary film. Profiling is produced either by a comblike jet lip (Barfilex process [201]) during extrusion or by roll embossing [202], [203]. In both cases, the impressed longitudinal grooves act as preset break points, which tear at the high draw ratios used (ca. 1 : 10). However, these processes are of minor practical importance compared to needle roll fibrillation.

Split fibers are obtained by cutting the fibrillated tapes in staple cutters (l). This process, however, is used rarely because of the development of short spinning technology to produce PP spun fibers of appropriate deniers at a reasonable cost.

End use for fibrillated tapes (split yarns) include twine, rope, reinforcement and weft yarn in woven carpets, and coarse yarn for geotextiles.

Coloration and Finishing. Tapes and split yarns are almost exclusively bulk-dyed with the aid of pigment concentrates, which are added prior to extrusion. The problem of coloring polyolefins by bath dyeing has not yet been solved satisfactorily.

Inorganic compounds such as chalk are added to reduce splitting and facilitate weaving. Ultraviolet stabilizers, required for many areas, are often provided by the manufacturer of the raw material, but the processor can also blend in concentrates. In general, UV stabilizers of the HALS type are used. They also impart good weathering resistance to PP ribbons [204]. However, HALS stabilizers may interact with certain pigments.

Antistatic agents and incorporated lubricants are generally not effective for ribbons and monofilaments. In addition, they can cause problems during film and ribbon production (e.g., plate out and water carry over). Subsequent external application (finishing) gives better results.

4.2.3. Uses

Tapes and split yarns of polyolefins are used in textile products that require high strength; low weight; chemical, moisture, and abrasion resistance; as well as other properties. Because of

the ease of processing and the low volume cost compared to other fiber raw materials, their use is especially economical in many cases.

To a large extent, PP and HDPE tapes have replaced jute, hemp, sisal, and other natural fibers. Film yarns and split yarns (tenacities commonly 4 – 6 cN/dtex) are used particularly in the manufacture of bags, flexible bulk containers and other packaging fabrics and knits; industrial fabric (e.g., tarpaulin, geotextiles, filter fabrics); carpet backing; netting (protection against hail, birds, solar radiation, etc.); awnings; camouflage shields; twine; rope and cable.

Packaging and Industrial Fabrics. Wide width fabrics are usually produced on flat looms [205]. Circular looms are useful for bagging, because in addition to simpler preparation for weaving (no beaming; weaving directly from the reel), elimination of the sideseam gives better bag strength and saves labor as well as material [206].

By subsequent extrusion coating, mostly with LDPE or PP, water- and dustproof fabrics are obtained. In addition, the coating prevents ribbon slippage and loosening of the fabric.

Carpet Backing. Because of the relatively high thermal stress during carpet manufacture (dispersion coating and drying), only PP ribbon can be used. The major application is as primary backing in the manufacture of tufted carpets; to a lesser extent, PP is used as secondary backing and as binding warp yarns in conventional woven carpets. The splitting behavior must be precisely controlled, especially in primary backings, and shrinkage must be low ($<1\,\%$ at 132 °C, 20 s, European Association for Textile Polyolefins method) [192]. Too little splitting leads to deflection of the tufting needles and, hence, defects in the carpet as well as breakage of individual tapes. Too much splitting also affects fabric strength adversely. Tenter setting, previously used to minimize shrinkage of the entire fabric, is employed only occasionally.

Knit Goods. Cloth for bagging or for shade, camouflage, and hail protection can be made on warp knitting machines as well as on looms [193], [207]. In most cases, netlike, coarse-stitch products, e.g., bags and pouches for fruit, vegetables, and other crops, are made.

The raw material is almost exclusively HDPE, frequently via the split-knitting process [193], [194]. Polypropylene tapes are difficult to fabricate on knitting machines because of poor sliding properties and tendency to split and break.

Twine, String, and Rope. Twine and string for packaging are obtained from highly stretched, spontaneously splitting, or fibrillated tapes of PP, by twisting and plying. For high-strength ropes and cables, fibrillated ribbons, PP monofilaments, and long staple fibers are used [208].

Floor Covering. Split fibers can, like other fibers, be processed into needle felts, which are used as floor or wall coverings. The use of split fibers in these areas has, however, decreased considerably and given way to spun fibers.

4.3. Monofilaments

4.3.1. Production

Monofilaments of PP or HDPE usually have a round or elliptical cross section, with a diameter of 0.1 – 3 mm (mostly 0.1 – 0.5 mm).

The steps in monofilament production are, for the most part, identical to those in tape manufacture. Monofilament machines consist of extruder, spinning unit (spinning head with spinning pump and spinneret), cooling bath, roll stretching units (usually two sets of seven rolls and one set of three rolls), hot-air ovens or a hot-water bath (for HDPE), and windups [184], [209]. Raw materials are generally propylene homopolymers with melt flow indices between ca. 2 and 6 g/10 min (MFI 230/2.16). If improved abrasion and rubbing resistance as well as better cold toughness are required, propylene copolymers are also used. Among the HDPE types, those with densities of 0.950 – 0.960 g/cm^3, MFI 190/2.16 values between 0.4 and 1.0 g/10 min, and narrow molecular mass distribution have been found to perform best.

Extruder – Spinneret. Extruders with a screw diameter of 45 – 90 mm are used for the production of monofilaments. Spinneret holes are arranged in concentric circles on the plate.

Depending on the size of the unit and the diameter of the monofilaments, ca. 50 – 100 monofilaments are extruded through one spinneret. In general, the spinneret hole diameter for polyolefins is three to four times the final diameter.

Cooling Bath. Monofilaments are produced exclusively with water bath cooling; the water temperature is 20 – 60 °C, depending on working material and thickness of the monofilaments.

Stretching. Stretching of PP monofilaments occurs in hot-air ovens between two stretching units with seven rolls each. The usual draw ratio is 1 : 8 to 1 : 12, and the temperature is 120 – 160 °C. Because of their lower softening range, HDPE monofilaments can be stretched in water baths at, or slightly below, 100 °C. Compared to stretching in hot-air ovens, this method has the advantage of better and more uniform heat transfer. Stretch ratios are generally between 1 : 8 and 1 : 11.

Setting. As in tape production, setting occurs in hot air after stretching. It is also done under tension, which is controlled by suitable adjustment of drawoff roll speed. Setting temperature is in the range of stretching temperature; setting shrinkage is usually adjusted to 4 – 8 %.

Windup. in contrast to film yarns (which are wound on packages with traverse laydown), monofilaments are usually wound in parallel on flanged disk spools. Windup speed is ca. 100 – 180 m/min. Monofilaments for bristles are wound on large-diameter reels or wheels to avoid too high a curvature.

Coloration and Finish. Coloring and finishing are similar to the process steps for tapes. However, addition of mineral fillers to reduce splitting is not required for monofilaments. To avoid fibrillation of the outer layers, surface finishes are applied (e.g., during twisting) to improve lubricity.

4.3.2. Uses

Monofilaments of PP and HDPE are processed into fabrics, knit goods, rope, and cable on the same machines used for film ribbons and split yarns.

Areas of application include fishing nets (HDPE); nets for protection from hail, birds, etc.; packaging nets; sieves and filter fabrics; rope and cable; bristles; reinforcing grids for construction sheeting; and tarpaulin.

Bristles for sweepers, road brooms, and the like are sometimes mechanically split at the ends. Because sufficient weathering resistance can be obtained with little or no UV stabilizer, HDPE is often used for protective netting.

4.4. High-Modulus Polyolefin Yarns

Conventional processes for producing polyolefin tapes, monofilaments, and fibers give a structure that consists of more or less oriented crystals as well as amorphous regions. Considerably higher values of the modulus of elasticity and tensile strength are to be expected if chain folding can be avoided, and as many molecular chains as possible can be oriented in the direction in which the load is applied. This ideal case can be approximated most closely with HDPE. Based on its relatively high packing density in the crystal lattice, HDPE should give the highest theoretical stiffness and strength value [210]. On the other hand, HDPE can be relatively easily prepared with very high molecular mass, so the number of chain ends and defects in the crystal can be minimized. The theoretically attainable stiffness and strength values of polypropylene are lower because of its helical structure. However, PP is also of interest because of its higher heat resistance.

The necessary "ultrahigh" orientation of the molecular chains can be achieved essentially in two ways with high molecular mass polyolefins: (1) drawing in the solid state (at a temperature clearly below the melting range) [211–214], and (2) spinning of highly viscous solutions (gel spinning) and subsequent one- or two-stage drawing [215], [216].

Higher modulus and strength are attainable by drawing in solution than by drawing in the solid state because products with higher molecular mass can be used, and a higher degree of orientation can be achieved.

4.4.1. Production

Two technologies are available; both are still in the process of commercialization. Drawing in the solid state is accomplished in draw jets at ca. 100 °C [217]. At draw ratios up to 1 : 30, moduli of ca. 50 GPa are attained for HDPE and ca. 20 GPa for PP. This process is being commercialized by the British Petroleum (BP) and Celanese companies.

In gel spinning (Fig. 26), a highly viscous solution in Decalin, paraffin oil, or paraffin wax is first prepared in a kneading or stirring unit [218]. It is then extruded through a spinneret (c) into a prepicitating bath (d). After entering the precipitating and cooling bath, the filaments are in a gel state in which the molecules remain largely disentangled. For orientation in the fiber direction and subsequent crystallization with final removal of solvent, a single- or multiple-step drawing process follows (e). Drawing occurs under heat and with a stretch factor $\geq$30. Preferably, HDPE with a molecular mass of ca. 2×10^6 is used (UHMMPE). The yarns can subsequently be cross-linked using radiation.

4.4.2. Properties and Uses

By gel spinning, HDPE yarns with moduli of elasticity of 50 – 100 GPa, and tenacities of $\leq$ 35 cN/dtex can be produced [219]. Because of their low density (0.97 g/cm^3), these yarns have an extremely high specific strength and are very abrasion, light, chemical, and moisture resistant. In addition, they exhibit high energy absorption and knot strength as well as good resistance to cold. Limitations in use include a relatively high tendency to creep and a relatively low melting temperature (ca. 150 °C). Radiation cross-linking increases heat resistance and reduces the tendency to creep.

End-use possibilities are extremely high-strength rope and cable, fabric for sails, industrial filters, bulletproof vests, and reinforcing layers for composites.

Trade names: Deyneema (DSM – Toyobo, The Netherlands – Japan); Spectra (Allied, United States); Tekmilon (Mitsui, Japan)

5. Polyacrylonitrile Fibers

"Polyacrylonitrile fibers" is a collective name for all fibers that contain at least 85 % polymerized acrylonitrile [*107-13-1*]. These fibers are also referred to as "acrylic fibers." Most polyacrylonitrile [*25014-41-9*] (PAC) fibers consist of ternary copolymers with 89 – 95 % acrylonitrile, 4 – 10 % of a non-ionogenic comonomer, and 0.5 – 1 % of an iogenic comonomer containing a sulfo ($-SO_3H$) or sulfonate ($-OSO_3H$) group. Fibers of 100 % acrylonitrile are also produced for industrial use [220]. Because polyacrylonitrile decomposes before melting, it cannot be spun from the melt but only from solution.

History. In the early 1930s, H. Rein at I.G. Farbenindustrie carried out experiments to produce fibers from polyacrylonitrile. Because of its insolubility in organic solvents, its nonmelting properties, and its high softening point, advantageous fiber properties were expected. Patents for the use of dimethylformamide (DMF) as a solvent for acrylonitrile polymerization were filed in Germany in 1942 by I.G. Farben and in the United States in 1944 by Du Pont. It was the first industrially useful solvent for the production of polyacrylonitrile fibers. Soon thereafter, dimethylacetamide (DMA) was also found to be a solvent. Technology for dissolving the polymer in aqueous ions of certain organic salts was also developed. The first acrylic fiber was commercialized by Du Pont in 1948. In the Federal Republic of Germany, production of acrylic fibers began in 1954 [221].

The composition of the copolymer (cf. Section 5.3.1) determines the dyeing behavior of the fibers. The non-ionogenic comonomer serves as an internal plasticizer and increases the rate of dye uptake. The sulfonate group of the ionogenic comonomer makes possible chemically bonding ionogenic dyes, whose color-imparting ion is a cation (basic dyes). The amount of iogenic comonomer determines the saturation value, i.e., the maximum amount of dye that can be chemically bonded by the fibers. Acidic ionogenic comonomers are replaced by basic comonomers if use of acid dyes is desirable.

Basic-dyeable acrylic fibers are the major type of fiber consumed; those made of 100 %

∗ Ultrahigh molecular mass high-density polyethylene.

acrylonitrile and those dyeable with acid dyes lag far behind.

The term "modacrylic" designates all fibers that contain 50 – 85 % of bound polyacrylonitrile. Fibers with 40 – 60 % copolymerized vinyl chloride and fibers with 30 – 45 % copolymerized vinylidene chloride are important because of their flame-retardant properties.

Polyacrylonitrile fibers are wool-like in nature. An important step in their development was the improvement in dyeability by modification with suitable comonomers. Their wool-like nature and good dyeability have established a secure place for acrylic fibers in the textile market along with polyester and polyamide fibers.

World production of acrylic fiber increased from 1 449 000 t/a in 1974 to 2 334 000 t/a in 1984 and to 2 383 000 t/a in 1992. In 1984, polyacrylonitrile fibers represented 14.9 % of all synthetic fibers produced and 6.5 % of total fiber production (synthetics, cotton, and wool); world production of polyacrylonitrile fibers exceeded wool production (1 672 000 t) by 662 000 t [222].

5.1. Physical Properties

Textile Characterization. Articles of acrylic fibers have a wool-like hand. Lower fineness fibers produce a softer hand; higher fineness make it harsher. The high bulk and low density (compared to natural fibers) make possible light, airy textiles with good recovery, warmth retention, and covering power. Because acrylic fibers do not swell, articles made from them remain permeable to air even when wet. The tensile strength of acrylic fibers and the abrasion resistance of articles made from them are greater than those of natural fibers.

Commercial fibers have different dye affinities and dye uptake rates. For light shades, dispersion and basic dyes are used; for dark shades, only basic dyes. Dyeing temperature is generally ca. 100 °C. Dyeings are distinguished by brilliance and fastnesses. The degree of luster is determined by the type, brilliant or delustered.

Articles of acrylic fibers fall into the easy-care category. They absorb little moisture, can be washed at moderate temperature, and dry rapidly. They are resistant to many organic solvents, and stains can be removed easily. They do not felt. Weathering and lightfastness are excellent and unsurpassed by any natural or synthetic fiber. This makes the fiber especially suitable for outdoor uses such as awnings. The fiber is not attacked by bacteria, mildew, or insects, and does not rot.

5.2. Chemical Properties [223]

Good chemical resistance of the homopolymer to hydrolysis permits industrial applications up to 140 °C in a humid atmosphere, e.g., for filter fabrics. The resistance of acrylic fibers to

industrial gases, smoke, and soot is very good. Acrylic fibers are resistant to moderate concentration of mineral acids and to oxidizing agents. They are soluble in concentrated sulfuric acid and concentrated nitric acid. Resistance to weak alkali is sufficient. Acrylic fibers are insoluble in most organic solvents, e.g., benzene, mineral oil, carbon tetrachloride, aliphatic hydrocarbons, aliphatic alcohols (e.g., ethanol), aliphatic esters, and aliphatic ketones (e.g., acetone).

In the burn test, the fibers melt, ignite, and burn with a yellow, sooty flame; a dark, hard, and brittle residue remains. In contrast, modacrylic fibers melt in the flame to dark, hard lumps; burn partially; but extinguish again if the flame is removed.

For a summary of the properties of acrylic and modacrylic fibers, see → Fibers, 1. Survey, Chap. 5.

5.3. Production

Production of polyacrylonitrile fibers includes the following processing steps (Fig. 27) [224]:

1) Polymerization (Section 5.3.1)
2) Dissolving (Section 5.3.2)
3) Spinning (Section 5.3.3)
4) Aftertreatment (Section 5.3.4)

5.3.1. Polymerization

The fiber raw materials for acrylic or modacrylic fibers are produced by polymerization or copolymerization of acrylonitrile (→ Acrylonitrile). For further details concerning reactivity and material constants see [225].

Polyacrylonitrile can be made by anionic or radical polymerization. Although polymer solutions can be produced in high space–time yields by anionic polymerization, radical-initiated polymerization or copolymerization of acrylonitrile is generally the method of choice in the manufacture of raw materials for acrylic or modacrylic fibers. Either solution polymerization or precipitation polymerization is used.

Like all vinyl monomers, acrylonitrile can polymerize with the formation of isotactic as well as syndiotactic sequences. The processes used to produce acrylonitrile polymers give about equal amounts of isotactic and syndiotactic sequences [226].

For commercially useful acrylic fibers or yarns, homo- or copolymers of acrylonitrile are used as raw materials. The raw materials for acrylic fibers in *textile applications* are acrylonitrile terpolymers.

The same initiator systems and similar reaction conditions can be used for the industrial unipolymerization of acrylonitrile as are used to produce acrylonitrile copolymers, the raw materials for the usual acrylic fibers in textile applications.

Interest has developed in very high molecular mass acrylonitrile copolymers that contain small amounts of comonomers. These materials are used to produce high-strength acrylic yarns [227].

To obtain the desired properties in acrylic fibers for textile applications, acrylonitrile terpolymers are used as raw materials. These polymers contain 4 – 10 % comonomers, are free of ionic groups, and are particularly suited for statistical copolymerization with acrylonitrile. Examples are the methyl esters of acrylic or methacrylic acid, vinyl acetate, or acrylamide. Depending on the need for raw materials for cationically or anionically dyeable acrylic fibers, an acidic or basic comonomer is used as an additional component (cf. Section 5.5). Monomers containing sulfonic acid groups have proved particularly usefull as acidic or anionic comonomers, e.g., methallyl sulfonic acid, styrene sulfonic acid, and 2-methyl-2-sulfopropylacrylamide, or soluble salts of these sulfonic acids, respectively. Examples of basic comonomers are dialkyl aminoalkyl methacrylates or vinylpyridines.

Although the processing technology of the terpolymerization reaction is largely independent of monomer composition, special attention must be given to the structure of the dyeing comonomer when selecting the initiator or initiator system.

Precipitation Polymerization. In the precipitation polymerization of acrylonitrile in water to produce acrylic fiber raw materials, use is made of the relatively good water solubility of the monomer. To introduce end groups into the fiber raw material, which can be utilized to adjust dyeability properties initiator systems are

used. The polymerization is initiated with water-soluble peroxy disulfate redox systems, such as potassium, ammonium, or sodium peroxydisulfate, combined with water-soluble salts of sulfur (IV) or derivatives of sulfur (II). Especially useful in the production of raw materials for cationically dyeable acrylic fibers is the initiator system peroxydisulfate – hydrogen sulfite. The decomposition reaction of this redox system has been thoroughly studied [228].

The relationship between dyeability and the number of different end groups in the copolymers is known [229]. The type and concentration of polymer end groups of the fiber raw material have a major influence not only on the coloring properties but also on the resistance to thermally induced yellowing and the degree of whiteness of the resulting acrylic fibers.

To obtain cationic dyeable acrylic fibers, precipitation polymerization is carried out at 40 – 70 °C and at a pH of <6. Peroxydisulfate – hydrogen sulfite is used as initiator of polymerization with a severalfold molar excess of hydrogen sulfite relative to peroxydisulfate. To purify and demonomerize the polymer completely and

gently, a compact polymer granulate, which can be dried after washing and filtering, is produced.

In the synthesis of fiber raw materials for acrylic fibers that are to be dyed with anionic dyes, redox systems, e.g., H_2O_2 – thioglycerine [230], that do not result in anionic end groups are used.

A detailed description of redox polymerization of acrylonitrile and a comprehensive review of the use of redox systems can be found in handbooks [231]. The constancy of distribution of molecular mass, chemical composition, and degree of whiteness is particularly significant to the final properties of acrylic fibers [220, p. 200].

Solution Polymerization. The copolymerization of acrylonitrile in solution results in polymer solutions that can be spun without additional process steps after the elimination of residual monomers. The polymerization reaction conditions must be optimized so that monomer conversion is almost complete; low molecular mass fractions that could adversely affect the mechanical and thermal properties of the resulting acrylic fibers must be avoided as much as possible. Examples of suitable solvents are dimethylformamide, dimethyl sulfoxide, nitric acid, and concentrated aqueous solutions of ammonium thiocyanate or zinc chloride. In radical polymerization, these solvents – but especially the polymer solutions – are effective chain-transfer agents. For that reason, specially selected initiator systems and special reactors are used for the large-scale commercial solution polymerization of acrylonitrile [232].

The choice of precipitation polymerization or solution polymerization often depends on the prior history of the acrylic fiber producer. Both processes have advantages and disadvantages, and economics – size of installation, type of spinning process in use and raw material situation – is often the deciding factor.

5.3.2. Dissolving

The solvents used in dry and wet spinning are listed in Table 15.

Commercial process. A dough, which is as free of clumps as possible in order to avoid long dissolution times, is prepared from the powdery polymer and the solvent by growing a compact polymer granulate; intimate mixing of polymer and solvent stream, e.g., in screw mixers, turbines, or paddle mixers; and, providing low solvent temperature, which initially produces a suspension with good distribution of polymer in the solvent.

A two-step process is used for dissolution in aqueous salt solutions. The polymer is first suspended in a salt solution that does not dissolve the polymer; then the salt concentration is increased to the amount necessary for dissolution. This process takes place in agitating pans, either batchwise or continuously. The batchwise process requires several hours to produce dimethylformamide solutions. The dissolving temperature is between 60 and 100 °C. In the continuous process, the holdup time in the agitating pan is shorter (e.g., 5 – 30 min), but the temperature of dissolution is correspondingly higher (e.g., up to 120 °C) and the intensity of agitation is greater [233]. The solution can then be treated thermally in heat exchangers or exposed to shearing forces in screws or turbines.

The concentration of the spinning solutions is higher for dry spinning than for wet spinning. When dimethylformamide is the solvent, 25 – 30 % solutions are normally used for dry spinning and 20 – 25 % solutions for wet spinning. Concentration and viscosity of the spinning solution are monitored constantly.

To keep the spinning solutions free of gel particles or other impurities, which is a prerequisite for long spinneret life, they are filtered in filter presses. Heat, amines, oxygen, and ions of heavy metals (especially iron) damage initial color (degree of whiteness). Therefore, an inert atmosphere, acid, and reducing and complexing stabilizers are needed [234], [235]. Additives have also been developed to protect against salt-like clouding of the solutions (in dimethylformamide) because of the polymerization catalyst [236], [237].

Stable viscosity is desirable so that spinning remains a steady-state process; it is obtained by optimizing the temperature of dissolution (ca. 70 – 100 °C) or by using suitable additives [238], [239].

Gelation occurs at low temperature via secondary valence forces and at high temperature via cross-linking reactions. The higher the viscosity of the solution and the molecular mass of

* Aqueous solution.

the polymer, the greater is the tendency to gel; more uniform polymers have less tendency to gel [240].

Aqueous zinc chloride solutions and solutions in dimethyl sulfoxide and ethylene carbonate also tend to gel. Because partial hydrolysis of the nitrile groups occurs when nitric acid is used as the solvent, these spinning solutions should not be heated above 5 °C.

5.3.3. Spinning

The polymer contained in the spinning solution is shaped into a yarn by either wet or dry spinning. In both processes, the spinning solution is pressed through small holes in the spinneret, thus giving the polymer its threadlike shape. The processes differ in the state of aggregation of the medium that the spinning solution enters on leaving the spinneret. In wet spinning, a precipitating bath of water and the solvent is involved; in dry spinning, hot air or a hot inert gas.

Wet Spinning. The solvents used industrially for wet spinning are listed in Table 15. Examples from the patent literature of spinning conditions for various solvents are given in Table 16.

The 10 – 25 % polymer solutions are deaerated, filtered, and pumped through the 10 000 – 80 000-hole spinnerets into the precipitating bath, where the solution thread line is coagulated to a highly swollen gel yarn by the exchange of solvent in the yarn for water. Coagulation conditions determine the strength of the sheath – core structure of the yarn, as well as its porosity and cross-sectional shape. Wet-spun yarns are aftertreated immediately without intermediate storage.

Dry-Jet Process.

In a variation of the wet-spinning process, the solution thread line leaving the spinneret is first passed through air before entering the precipitating bath. Fibers with higher strength and elongation, smoother surface, and greater uniformity can be made by this process [241].

Dry Spinning. The only solvent used in dry spinning of polyacrylonitrile fibers is dimethylformamide having the following properties:

bp (101.2 kPa)	153 °C
Heat of vaporization	571.24 kJ/kg
Water	<0.3 %
Amines	<0.01 % dimethylamine
Iron	<0.05 ppm

The pH of a 20 % aqueous solution at 25 °C should be 6.5 – 9.

The degassed and filtered spinning solution is heated to 100 – 150 °C and spun into vertical spinning shafts through spinnerets (200 – 2000 spinneret holes; hole diameter, 0.1 – 0.5 mm). Several spinning shafts make up a spinning machine. The walls of the shafts are heated to 150 – 220 °C; hot air or a hot inert gas (200 – 240 °C),

Table 16. Solvents and conditions for wet spinning

Solvent [a] (wt %)	Concentration [b], wt %	Composition [c], wt %	Temperature,[c] °C

[c] Of the precipitation bath.

passes through the shaft in the same direction as the yarn. The oxygen and water content of the spinning gas should be as low as possible to avoid discoloration of the spun yarn and decomposition of dimethylformamide. Dimethylformamide evaporates in the spinning shaft and is exhausted together with the spinning gas at the bottom of the shaft. The performance of a spinning shaft is, in the final analysis, determined by the geometry of the engineering apparatus and by the amount of heat transferred to the spinning threads via the hot gas and radiation from the heated walls of the shaft. Of special significance for the quality and performance of the spun material is the air guidance in the immediate vicinity of the spinneret [242–244].

Solidified, dried spun yarns are drawn off at a rate of 200 – 500 m/min. Spun yarns from the shafts of one spinning machine are collected and deposited in a can. (In the manufacture of continuous filaments, spinnerets with a maximum of 200 holes are used. In this case, an oily finish is applied to the spun material below the spinning shaft, and it is wound up on bobbins.)

The dimethylformamide that has evaporated is condensed, distilled, and recycled. The spun material still contains 7 – 30 % DMF, which is leached out during aftertreatment and recovered by distillation.

The spinning conditions (temperature of solution, temperature of shaft, temperature and amount of spinning gas, and drawoff speed) greatly affect both further processing of the spun yarns (e.g., drawability) and properties of the end product (e.g., strength and elongation).

Melt spinning. Mixtures of polyacrylonitrile and water (ca. 13 – 33 % relative to the polymer), in contrast to anhydrous polyacrylonitrile, can form a molten, single-phase system without decomposition of the polymer. Fibers from a polyacrylonitrile – water mixture were prepared as early as 1948 and again around 1970 – 1971 [220, p. 260 ff]. The advantage of such a process could be the absence of solvent and lower costs. However, more than 15 years of research and development have not yet resulted in a commercial process. Possible reasons for this are the high viscosities of the melts and the difficulty of preventing the melt from becoming two-phase at any point in the process.

5.3.4. Aftertreatment

The aftertreatment steps are as follows:

1) Washing
2) Drawing
3) Finish application
4) Crimping
5) Drying
6) Cutting
7) Steaming
8) Packaging

Cutting is omitted in the production of tow.

During aftertreatment, the spun material acquires the necessary physical properties, such as strength, modulus, elongation, shrinkage, crimp, and crimp stability. Large-scale aftertreatment units are capable of processing tow up to 770 ktex (770 g/m) at rates up to 120 m/min in dry spinning and up to 80 m/min in wet spinning. The daily production of a large unit is 110 – 120 t; smaller units (30 t/d) are also used [245].

Washing. Washing removes residual solvent and salts by leaching with hot water (e.g., 80 °C) in multilayer or drum washing machines. A closed construction is used to protect the environment. The washing machine consists of many individual zones. The wash water travels in a direction opposite to the direction of travel of the yarn tow. The wash water is distilled or otherwise processed to recover the solvent. Washing usually precedes drawing because of the longer holdup time in the washing baths resulting from the relatively low tow speeds prior to drawing, which makes the washing process correspondingly more intense.

Drawing. Drawing imparts the required strength to the yarn and occurs in two or more steps in drawing tanks between drawing units. The preferred drawing medium is water just below the boil (e.g., 99 °C). The draw ratio is between 1 : 2 and 1 : 10. Wet-spun yarns must be drawn more (because of the absence of preorientation) than dry-spun yarns to attain the same strength. The rule "the higher the draw, the higher are the strength and modulus and the lower is the break elongation" applies to both processes.

After being drawn, the yarns have a boil-off shrinkage, which, depending on the draw ratio, is between 15 and 45 %. Shrinkage increases as draw temperature decreases and passes through a maximum with decreasing draw ratio. This behavior is applied to production of shrinkable fibers. Fibers already shrunk can be made shrinkable by a postdrawing treatment.

In addition to water drawing, steam drawing or drawing on feed wheels is also possible.

Finishing. Finish application occurs in an immersion bath. Most commonly, active anionic compounds are applied to the fibers from an aqueous medium. Examples are ethoxylated fatty acids, salts of ethoxylated sulfonic acids, or phosphoric acid esters of long-chain aliphatic alcohols. Finish application prevents the buildup of static charges during further processing of the fibers and imparts the proper degree of adhesion and smoothness to the surface. The finish content of the finished fiber is 0.2 – 0.4 %. It can be determined by extracting with ether or a mixture of methanol – benzene, evaporating the solvent, and weighing.

Crimping. In general, crimping is carried out in a stuffer box after drying (stuffer box crimping). A steaming zone, in which saturated steam condenses on the tow, heats the tow and makes it more formable. Two crimping rolls, kept at constant temperature by circulating cooling water, pull tow bands of up to 3×10^6 dtex into the crimping chamber, stuff them, and push them continuously from the chamber at a predetermined pressure. In certain crimping units, steam can be introduced into the stuffer box to shrink the tow and increase the crimp stability (setting).

The type of crimp is important in processing fibers because of its effect on cohesion and on the hand of the yarns produced from the fibers. Crimp is determined by the conditions of crimping (temperature and stuffing box pressure), the percentage of comonomer in the polymer, and other factors that affect the thermal plasticity or friction, e.g., moisture content or type of finish.

Drying. Screen drum dryers, screen belt dryers, or calenders are used for drying. Drying temperatures of 120 – 170 °C are common.

During tensionless drying, i.e., drying loosely laid tow bands or cut fibers, the shrinkage built into the fiber in the drawing process is released and removed. This process can be enhanced by steaming. When dried under tension, the fibers

must subsequently be relaxed, usually by steaming. Drying reduces the moisture content of the fibers to 1 – 2 % and increases their density.

Although polyacrylonitrile does not crystallize like polyamide or polyester, an improvement or increase in regions of near-order by drying or annealing can, nevertheless, be demonstrated by X-ray analysis. Because of the consolidating effect of drying, uniform drying is especially important for uniform dyeability of the fibers.

Steaming. Steaming generally occurs in screen belt steamers or in autoclaves. Steaming with saturated steam shrinks the fibers and increases the crimp stability. To ensure that the shrinking process is complete, a high and uniform steam atmosphere (>95 % steam) is required.

Steaming increases the elongation of the fibers and slightly reduces their strength. Steaming under pressure is especially effective in increasing the rate of dye uptake.

Cutting and Packaging. In the production of endless tow for processing on stretch – break machines, the crimped and dried tow bands are packaged in cartons or bales. The mass of such tows ranges from 50 to 110 g/m. The bundle mass is 100 kg per carton and up to 800 kg per bale.

In the production of staple fibers, the crimped and dried tow bands are cut into staple fibers with slotted wheels or rotary cutters. The usual cut lengths are 40, 60, 80, 100, or 150 mm, depending on end use. Cut fibers are compressed and packaged into bales of ca. 200 – 300 kg in packing presses.

The aftertreatment of *filament yarns* of polyacrylonitrile involves processes similar to those for tow and fibers: drawing and setting. Equipment is tailored to the particular filament count of the product. In addition, the filaments are twisted to tighten the yarn and packaged on cones, which are shipped at a mass of 1.5 – 2.0 kg. Commercial counts of industrial filaments are 220 dtex/96 filaments, 440 dtex/192 filaments, or 890 dtex/384 filaments.

5.3.5. Special Processes

Continuous Dry Spinning Process. Modern continuous dry spinning and aftertreatment processes have eliminated storage following the dry-spinning process [246].

Because of the relatively high spinning speed (compared with wet spinning), the tow speed after drawing must be 500 – 2000 m/min. A vibrating trough is used to transport the spun tow during washing. Drawing is carried out in steam; crimping, in an aerodynamic crimper with a gaseous medium (at 1.5 – 1.6 MPa and 50 – 210 °C). Finish application can occur before, during, or after crimping. The steaming process is carried out in a vibrating trough in a steamer; drying, in a belt dryer.

In this process, products of uniform quality are obtained; solvent emission and waste are reduced; and manufacturing costs are lower [246].

In one variant of this process, washing is also eliminated [247].

Producer Coloring. The manufacture of colored fibers is of economic interest if large amounts of one color are to be produced. Fiber producers can make colored fibers in the following ways:

1) Spin dyeing,
2) Gel dyeing,
3) Dyeing of spun material

Spin Dyeing [248]. Dyes, either cationic or pigment dyes, are added to the spinning solution prior to spinning.

The dyes are free of adulterants. They are soluble in the solvent used and should be insoluble in water (the subsequent washing medium). Dye solutions also contain polymer to adjust their viscosity to that of the spinning solution. In general, combinations of dye solutions are metered into the polymer solution to achieve a given color; they are homogenized by means of statically or mechanically operating mixers.

Ionic bonding of the color-imparting cation to the sulfite or sulfate groups of the polyacrylonitrile polymer is rapid and quantitative. Uniformly dyed tows with brilliant color and good textile fastness are obtained by both the dry-spinning and the wet-spinning processes.

Organic pigments are used when especially high lightfastness is required, e.g., in textiles used outdoors. The pigments are dispersed in a dilute solution of polymer. In so doing, stabilizers are added to prevent coagulation of the

dispersed dyes. This is followed by metering into the spinning solution as with cationic dyes.

Gel Dyeing. Dyeing during aftertreatment generally occurs while yarns are in the gel state after wet spinning. Dyeing is possible because cationic dyes rapidly diffuse into the highly swollen yarn. It can occur in the precipitating bath, the drawing tank, or a separate bath. It must be carried out prior to drying, which collapses the structure of the swollen yarn.

Dyeing by both the extraction method and the padding method has been patented. Important variables are temperature, concentration of dye, and time in the dye bath; these determine the amount of dye required and the wash- and light-fastness of the dyed material [249]. The choice of dyes is also important in the quality of dyeing [250].

Gel dyeing has the following advantages [251]:

1) Good dye uniformity within the batch and from batch to batch
2) Same tow quality as with undyed fibers because all physical perturbations are avoided
3) Economical batch size ($\geq$5 t) because hardly any material is wasted during dye change

Dyeing of Spun Material. Dry-spun yarns can also be dyed during aftertreatment, but the rate of dye uptake must be increased by suitable measures [252].

Uses. Fibers dyed in the course of fiber manufacture are used in clothing, home furnishings, and outdoor textiles. Yarns, pigment-colored during spinning, are recommended for outdoor textiles (awnings, sunshades, camping and terrace furniture, camping tents, and boat covers).

5.4. Analysis

Cross Section (Fig. 28). The cross-sectional structure of polyacrylonitrile fibers and modacrylic fibers is determined by the composition of the polymer, the spinning process, and spinning conditions. The shape of the cross section determines the luster, moisture regain, and mechanical properties of the fiber [253].

Figure 28. Acrylic fibers, cross sections and surfaces
A) Dry spun, delustered; B) Surface of A; C) Wet spun; D) Bifilar, dry spun, single component, delustered; E) Modacrylic, dry spun; F) Modacrylic, wet spun, delustered

Stress – Strain [220, pp. 73, 208]. The stress – strain curve of acrylic fibers (Fig. 29) is characterized below their glass transition temperature (50 – 95 °C with decreasing moisture content) by a steep initial region A, followed by zone B, where small changes in stress result in large changes in elongation. Above the glass transition temperature, A no longer exists; the fiber is more extensible, with slowly increasing resistance until a yield stress σ_c, at which structurally determined resistance to plastic sliding processes are overcome, is attained.

Figure 29. Stress – strain diagram of polyacrylonitrile (PAC) fibers [220]
A) Yield points below glass transition temperature $T < T_e$;B) Yield points above glass transition temperature $T > T_e T_e$ = second order transition temperature; σ_B and σ_C = points at which small increases in stress result in large changes in elongation

The stress – strain curve is affected by the type and amount of comonomer, the molecular mass and molecular mass distribution and the conditions of spinning and aftertreatment. Figure 30 shows the effect of the draw ratio.

Figure 30. Effect of three different draw ratios on elongation and stress

Thermomechanical Analysis [220, pp. 77, 209]. In thermomechanical analysis (TMA), the change in length of a fiber under a constant preload is observed at a constant rate of heating. From the changes in length of fibers under low load, conclusions can be drawn concerning their degree of heat-setting. In Figure 31, brands 1 and 2 were more intensively heat-set during manufacture than brand 3, in which extension of the yarns above 110 °C is prevented, principally by release of shrinkage tension.

Figure 31. Thermomechanical deformation of acrylic fiber tow of three different brands ∗ [220]
– – – – Brand 1; — · — Brand 2; —— Brand 3
∗ Pretension 0.015 cN/dtex; rate of heating 10 °C/min.

Analytical Procedure. The *cross section* of the fiber material provides a good indication that an acrylic fiber is present. Dumbbell-shaped cross sections indicate a dry-spun acrylic fiber; beanshaped cross sections, a wet spun fiber (cf. Figure 28).

Type reactions can be used to recognize and distinguish an acrylic fiber from other synthetic fibers. Each of these reactions, must be carried out on a freshly prepared sample; acrylic fibers should be [223]:

1) soluble in concentrated nitric acid at room temperature,
2) insoluble in concentrated formic acid at room temperature, and
3) insoluble in boiling cyclohexanone.

Analysis of *polymer composition* is carried out by IR spectroscopy [254]. A first indication of the composition of the copolymer is obtained from analysis of the acrylonitrile content. To determine the brand, the exact composition of the polymer is required. The major neutral comonomers are vinyl acetate, methyl methacrylate, and methyl acrylate. Major ionogenic comonomers are styrene sulfonate, methallyl sulfonate, and itaconate, or in acid-dyeable types, cyclic or aliphatic amines. In addition, the following are present in flame resis-

tant types (modacrylic fibers): vinyl bromide, vinyl chloride, and vinylidene chloride [255].

The number of ionogenic groups can be determined titrimetrically. Acid groups can be determined potentiometrically in DMF solution with 0.1 M NaOH [256]; basic groups, in nitromethane with perchloric acid in dioxane solution [257]. The quantitative determination of sulfur-containing polymer building blocks can also be accomplished by ignition in an oxygen flask and determination of the sulfate formed or by determining the sulfur with X-ray fluorescence analysis [258]. Indications of the "physical history" of an acrylic fiber are obtained by physical methods, e.g., thermomechanical analysis (previously discussed) or by determining the degree of relaxation with a solubility test [259].

The percentage of acrylic or modacrylic fibers in fiber blends can be determined by selective dissolution in DMF or DMA [260]. For comprehensive information on analysis, see [220, pp. 379 – 423].

5.5. Types of Fibers [261]

Classification. The multiplicity of acrylic fibers can be classified by various systems. Chemical composition determines certain properties that are used in classification; fibers can be

1) basic dyeable,
2) dark dyeable,
3) acid dyeable,
4) self-crimping, or
5) flame retardant.

Characteristic descriptions, such as brilliant, delustered, bright, and spun-dyed, are also used.

Subdivision into spun fiber and tow accounts for various processing possibilities: (1) spun fiber for woolen, cotton, worsted, and open-end (rotor) spinning processes; and (2) tow for processing on stretch – break machines followed by spinning. Classification can be by fineness (denier) range (in decitex):

1) Finest: 0.4, 0.6, 0.9
2) Fine: 1.6, 2.2, 2.6
3) Medium: 3.3, 5.0, 6.7
4) Coarse: 11.0, 15.0, 17.0

Cut lengths are 28, 40, 50, 60, 100, 120, and 150 mm.

Physical modifications important to the quality of the goods are also used in classification. The following distinctions are made with respect to fiber shrinkage:

N-fiber	0 – 2 % shrinkage
S-fiber	ca. 20 % shrinkage
HS-fiber	ca. 40 % shrinkage

The type of crimp is another criterion that affects the quality of the goods. Qualitative data on crimp and crimp stability (low, medium, or high) serve as characterization parameters.

The range of finenesses for tow for stretch-breaking is 1.5 – 17 dtex. Tow can be bright, delustered, or spun-dyed.

The number of combinations of various characteristics for basic dyeable fibers alone runs into several hundred. Some inkling of the extraordinary diversity of possible applications of the most important synthetic staple fiber can be obtained by considering that the processor has available more than 20 different brands with varying properties, that polyacrylonitrile fiber types can be blended with each other or with other synthetic or natural fibers to achieve certain properties, and that the quality of the goods is substantially affected by the many possible yarn and fabric constructions.

Industrial Fibers. Fibers for industrial use consist mostly of 100 % or almost 100 % acrylonitrile. Molecular mass is made as high as processibility will permit because the higher the molecular mass, the higher the strength. The fibers absorb very little moisture and, therefore, do not swell. They are resistant to hydrolysis, especially in acid medium, and are heat resistant up to 140 °C.

Uses. Fibers are used in filter hoses and filter pockets in dry filtration, e.g., in the separation of fly ash in coal-fired power stations. Another end use is in dryer felts in paper machines, which absorb water that could not be squeezed out of the paper sheets. Fibers of 100 % acrylonitrile are also used as asbestos replacement. For this end use, particularly high modulus and strength are required [262]. Nonmelting fibers that are nonflammable in air are obtained by

heat-treating acrylic fibers in an oxidizing atmosphere at 300 °C. These fibers can also replace asbestos [263]. Filaments of 100 % polymerized acrylonitrile are good starting materials for high-strength carbon fibers [264].

Dyeing Modifications. Dyeability is generally achieved in polyacrylonitrile fibers by inclusion of a neutral, plasticizing comonomer (5 – 10 %) and an ionogenic comonomer (e.g., methallyl sulfonic, 0.5 – 1.0 %) that has an affinity for dyes. By increasing the amount of comonomer with dye affinity to 3 – 4 %, fibers are obtained with a four- to fivefold increase in rate of dye uptake. Such fibers can be dyed at a temperature as low as 85 °C rather than at the boil. Dye migration is especially good in such fibers, and the time required to fix dyes is markedly reduced. Use of a rapidly absorbing fiber is based on the differential dyeing effect, which occurs when the fiber is dyed with a conventional fiber. Special-effect yarns can be produced from homogeneous or inhomogeneous blends of fibers or rovings, e.g., yarns of mixed colors, slub yarns, and flake twist yarns. Combinations of yarns result in twisted yarns with multicolor effects.

Another dye modification is represented by acid-dyeable fibers that contain 5 – 15 % of a basic comonomer with affinity for acid dyes. Possible comonomers are the vinylpyridines, e.g., 2-methyl-5-vinylpyridine [*29994-42-1*], or even aliphatic amines, e.g., 2-(dimethylamino)ethyl methacrylate [*2867-47-2*]. Yarns of acid-dyeable acrylic fibers are processed and dyed together with yarns of basic-dyeable acrylic fibers. Dyeing is carried out in the same dye bath containing both acid and basic dyes. In this way, interesting color effects can be achieved such as two-color effects or tone-on-tone effects. If an undyed – colored combination is desired, only acid dyes are used, to which a conventional acrylic yarn is relatively insensitive.

Modacrylic Fibers [265]. Modacrylic fibers contain 50 – 80 % bound acrylonitrile. The comonomer that makes up the difference is essentially a halogen-containing monomer. Vinyl chloride [*75-01-4*] and vinylidene chloride [*75-35-4*] are the most frequently used halogen-containing comonomers. The main advantage of modacrylic fibers is their reduced flammability. Whereas polyacrylonitrile fibers melt in the flame, ignite, and continue to burn after removal of the flame, modacrylic fibers are self-extinguishing once the flame is removed. In addition, they do not exhibit an undesirable dripping of molten fiber. The burnt residue is solid and black. In case of fire a disadvantage is the formation of hydrogen chloride. Fibers containing vinyl chloride exhibit even less flammability than vinylidene chloride fibers.

Bromine-containing monomers, e.g., vinyl bromide or vinylidene bromide, are also used. The development of polymerizable phosphorus compounds has become known as well.

In addition to acrylonitrile and halogen-containing comonomers, modacrylic fibers generally contain other comonomers that are intended to improve the dyeability of the fibers. These are mostly monomers with acid groups, e.g., sodium styrene sulfonate [*2695-37-6*] or sodium methallyl sulfonate [*149-44-0*]. Neutral comonomers, e.g., alkyl acrylamides, which improve dyeability by loosening fiber structure, can also be included. The manufacture of modacrylic fibers in essence follows the same process steps as the manufacture of polyacrylonitrile fibers.

Because of the type and high percentage of comonomer, modacrylic fibers exhibit higher plasticity, which is expressed as lower sticking temperature or higher shrinkage (for other properties, see → Fibers, 1. Survey, Chap. 5.). Attempts were made to eliminate this disadvantage by reducing the halogen content of the polymer and including additives in the spinning solution that act synergistically to reduce flammability. Such additives are antimony trioxide, organic antimony compounds, or halogen compounds of antimony or tin. Halogen compounds can form the oxide and can be dispersed in the fiber so finely that they do not act as delusterants. Even compounds of metals, e.g., barium titanate, or phosphorus compounds, e.g., derivatives of the acids of phosphorus, serve as flame retardants.

Modacrylic fibers tend to lose their luster under hot – wet treatment, even during dyeing. Salts are added to the dye bath or dyeing is done at lower temperature to prevent this. However, the best route is to reluster the dyed fibers with dry heat. Luster stability has been improved by changes in spinning and aftertreatment technol-

ogy, by specific changes in polymer composition, and by the addition of luster stabilizers.

Uses. Reduced flammability favors the use of modacrylic fibers wherever there are fire hazards or where the danger in case of fire is particularly severe. This includes such uses as children's sleepwear; home furnishings, especially drapes; wall coverings in public buildings; and automobile upholstery. A large area of application is in pile fabrics, carpets, and imitation furs. Modacrylics are also used in wigs.

Modacrylic fibers are processed by themselves or in blends with other fibers, e.g., acrylic fibers, polyester fibers, or poly(vinyl chloride) fibers. By blending and proper construction of the finished article, special processing requirements, as well as the requirements of flammability tests, can be met.

Absorbent Fibers [220]. To produce fibers with greater wear comfort, special attention has been paid to developing moisture-absorbent fibers. Such fibers must be able to absorb moisture from the air and from water, either by virtue of their ability to swell or by means of a system of pores in the interior of each fiber. With acrylic fibers, the formation of a pore system is especially significant.

The system of pores must be protected by a sheath of proper thickness to ensure that the fiber can be processed without problem. The sheath must have a multiplicity of fine channels that can conduct water into the porous interior of the fiber. The properties of such a fiber include high adsorptivity, no swelling, high threshold of clammy feel, rapid transport of water, rapid evaporation, and low density [266].

The manufacture of absorptive fibers by both dry- and wet-spinning processes has been described. In dry spinning, an appropriate precipitant can be added to the spinning solution. This results in the formation of a sheath around the filament and an internal system of pores during spinning [267]. In wet spinning, highly swollen yarns with many pores are first formed during coagulation in the precipitating bath [268]. By skillful tuning of processing conditions, these pores can be retained in the final product. Water-soluble substances can also be allowed to diffuse into the swollen filaments, which are then dried. By subsequent leaching of water-soluble compounds, a system of pores is created.

Fibers with high swellability can be produced by the inclusion of comonomers with hydrophilic groups. Examples of such comonomers are acrylic acid, methacrylic acid, or 2-(dimethylamino)ethyl methacrylate. The saponification of comonomers on the fiber produces hydrophilic carboxyl groups. A popular route to the production of water-absorbent fibers is the spinning of mixtures of polyacrylonitrile and other polymers. Addition of cellulose acetate favors pore formation. Addition of hydrophilic polymers, e.g., saponified acrylonitrile, favors water absorption.

Bicomponent Fibers. The side-by-side type of bicomponent fibers in which both components are placed eccentrically in the cross section and run along the entire length of the fiber, is commercially important (see Fig. 28D). Differential shrinkage of the components forming the fiber produces three-dimensional crimp when the shrinkage is released. The differential shrinkage of the two components is achieved by a difference in the amount of comonomers. If the concentration of hydrophilic, usually ionic, groups differs in the two components, reversible crimp results. This refers to a crimp that can be removed by washing and regenerated by drying. If the concentration of hydrophilic groups of the two components is essentially equal, the crimp is irreversible, i.e., permanent. The shrinkage of the fiber, and hence the crimp, can be released during fiber manufacture by drying or steaming or during subsequent processing, e.g., dyeing of the fiber or yarn.

Bicomponent fibers are produced both as staple fibers and as tow. Knit fabrics of these yarns are distinguished by good volume, pleasant, wool-like hand, and good stitch definition. Bicomponent fibers are also used in carpets because of covering power [269], [270]. The market for these fibers is primarily in Japan and the United States.

Shrinkable Fibers. Shrinkable fibers can be produced from tow by processing on stretch-break machines. In general, the fiber shrinkage produced on these machines is 15 – 24 %. If suitable measures are taken during tow production and stretch-breaking, fiber shrinkages of 24 – 40 % are attainable.

Shrinkable staple fibers are generally offered at two levels of shrinkage: (1) shrinkable fibers with ca. 20 % shrinkage and (2) high-shrink fibers with 35 – 40 % shrinkage. The desired level of shrinkage can be obtained most easily during the manufacture of shrinkable fibers by suitable choice of draw ratio and draw temperature with subsequent mild drying. Care must be taken, however, to produce a shrinkable fiber free of voids so that no electrostatic problems occur in further processing and no changes in coloration or luster occur in the processed fiber. Good technical properties are also desirable. Criteria for a void-free structure are negative birefringence and density $>1.180\ g/cm^3$ [271].

Shrinkable fibers are processed in blends with nonshrinkable fibers to give high-bulk yarns, which are distinguished by their high volume. High-shrinkage fibers are also used in imitation furs as bottom hair, in the production of multistep plushes, and in felts. Manufacturing methods are described in detail in many patents [220]. Important measures are consolidation of the yarn by removal of solvent, drying, and heat treatment in water or steam, partly prior to drawing and partly between two drawing steps. The rate of drawing is also important.

5.6. Economic Aspects

With 2 334 000 t (Western Europe 784 000 t), acrylic fibers amounted to 19 % of synthetic fiber (polyester, polyamide, and polyacrylic) production in 1984. Acrylic fibers are produced almost exclusively as staple fiber and tow. Acrylic fibers represented exactly one-third of the synthetic staple fibers in 1984 (6 977 000 t) [222].

Table 17. Consumption of acrylic fibers in the EEC (1983)

Use	Consumption, t/a	%
From yarns		
Fabrics	93 600	22.4
Knit goods	205 000	49.1
Carpets	26 300	6.3
Other	43 700	10.5
From fibers		
Fiberfill	1 300	0.3
Nonwovens	5 300	1.2
Other	42 600	10.2

In the European Economic Community (EEC) (Belgium, Federal Republic of Germany, France, Italy, Luxembourg, The Netherlands, and Great Britain), the consumption of acrylic fibers in 1983 is shown in Table 17.

Acrylic fibers are used both by themselves and in blends with others fibers. The major end use of acrylic fibers in clothing is in sweaters; in home furnishings, they are used in furniture covers and blankets [222].

Acrylic fibers represent the largest percentage (33 %) of fibers processed on knitting machines (Western Europe, 1983), ahead of cotton with 22.8 %. Other areas in which acrylic fibers represent the leading raw material, ahead of all other fibers, are furniture pile fabrics (80.0 %), knitted and woven furs (79.8 %), and awnings (85.0 %) [224].

The United States used ca. 207 000 t of acrylic fibers in 1985. Preferred areas of application were sporting goods (ca. 24 %), sweaters (ca. 17 %), hosiery (ca. 13 %), and knitting yarns (13 %).

World capacity of acrylic fibers is ca. 2.8×10^6 t/a. About one-third of this capacity is in Western Europe (major countries: Federal Republic of Germany, Great Britain, Italy, and Spain) and another third in Asia (major countries: Japan, South Korea, Taiwan, and Turkey). Important countries in North America are the United States and Mexico, and in the Eastern Block, the former Soviet Union. The major producers are shown in Table 18.

6. Poly(vinyl chloride) and Poly(vinylidene chloride) Fibers

According to standard ISO terminology, the generic name for poly(vinyl chloride) [*9002-86-2*] (PVC) and poly(vinylidene chloride) [*9002-85-1*] (PVDC) fiber is *chlorofiber*; this designates products containing at least 50 % vinyl chloride or vinylidene chloride units. In the United States, the Textile Fiber Products Identification Act defines any fiber containing at least 85 wt % of vinyl chloride units as *vinyon* and any fiber composed of at least 80 wt % of vinylidene chloride as *saran*.

Compared to acrylic or polyester fibers, the 1987 world production and consumption of chlorofibers is small, ca. 20 000 t/a.

Table 18. Major producers of acrylic fibers

Trade Name	Producer	Country	Process
Acrilan	Monsanto	USA	wet

In terms of comfort, flame retardancy, chemical resistance, and shrinkability, these fibers may be considered specialty items, essentially having the properties of the homopolymer, e.g., chemical composition, low crystallinity, high dipole moment, and low moisture regain. The obstacles to commercial development of these fibers result mainly from the low softening point, which leads to poor dimensional stability at elevated temperature and poor downstream processability compared to other synthetic fibers.

6.1. Fibers from Pure Poly(vinyl chloride) Homopolymer

6.1.1. Fibers from Pure Atactic Homopolymer

The poly(vinyl chloride) generally employed for fiber production is simply a variant of the standard polymer used in plastic compounds. Bulk polymerization at 60 – 70 °C is generally preferred because contamination from polymerization additives is low; this results in an atactic polymer with a molecular mass of 70 000 – 85 000. The melting point of pure homopolymer is close to the decomposition point. Dry or wet spinning from solution is, therefore, the only industrial route available to produce commercial fibers.

Dry Spinning. To avoid thermal decomposition with dehydrochlorination, the spinning temperature must be kept relatively low; therefore, the boiling point of the solvent also must be low.

Only a few common solvents are suitable for the homopolymer. Blends of equal volumes of carbon disulfide and acetone (*bp* 38 °C) and benzene and acetone (*bp* 64.5 °C) were patented and are presently used in production [272]. The spin-

ning composition consists of polymer, solvent, and additives. Polymer content varies with the molecular mass of the polymer and ranges from 25 to 30 wt %. The additives have definite functions, e.g., improving heat stability, lightfastness, whiteness, and luster [273]. Certain producers of homopolymer chlorofiber overcome the difficulties in conventional dyeing caused by the low shrinkage temperature of the fiber by adding dye to the spinning dope.

Early swelling of the complex polymer grain and high dope viscosity make dope preparation difficult. The three possible ways to overcome this problem are (1) flash mixing of polymer and solvent with a short residence time in the shearing system [274], (2) premixing the polymer with a nonsolvent [275], and (3) kneading under high shearing force with long residence time.

When the solution is processed at ambient temperature, the microcrystalline regions of the polymer are not dissolved and the solution is colloidal. Dissolution at a temperature >100 °C and processing the solution above the boiling point of the solvent result in a more homogeneous solution and a large decrease in viscosity, with concomitant advantages in further processing [276]. After the dope is dissolved, it is filtered in one or two steps.

The solution is heated or cooled to the spinning temperature and extruded through a 1000- to 2000-hole spinneret in a long tube with hot air moving concurrently with the filaments. The emerging filaments are cooled, wetted by an aqueous lubricant, and wound up or collected at 300 – 700 m/min. The spinning parameters are important because they determine characteristics of the as-spun filament, such as cross-sectional shape and specific surface.

Staple Route. After spinning, the tow is preheated at a temperature (80 °C) lower than the glass transition temperature and drawn 400 – 800 % at a temperature (85 °C) higher than the glass transition temperature. The drawing medium may be hot water or low-pressure steam.

After drawing, the fiber is thermally unstable and has a strong tendency to return to its original length; the shrinkage and shrinkage stress may be as great as 70 % and 0.6 cN/dtex, respectively. For this reason, the tow is annealed under tension in water or steam [277]. The residual shrinkage is removed by relaxing the fiber tension-free at the boil or slightly above.

The next steps in the production of standard fiber are oiling, drying, crimping, and cutting, by conventional technology. Some commercial interest has been shown in high-shrinkage (30 – 65 %) chlorofibers with their attendant high shrinkage stress. Shrinkable fibers are obtained by varying the draw ratio and avoiding the annealing and relaxation steps.

Wet Spinning. At present, one industrial plant (Kustanai, former States of USSR) uses the wet process to produce commercial chlorofiber. Suitable common solvents are *N,N*-dimethylacetamide (DMA) and *N,N*-dimethylformamide (DMF). Special additives are required to limit discoloration of the solution. With these solvents, the rate of coagulation is high and voids appear in the coagulated gel, permanently impairing fiber performance. To exert positive control over the coagulation rate, water is added to the solvent before the solution is prepared; the solvent is then heated to improve solubility [278]. High solvent content (up to 85 %) and low temperature (5 – 15 °C) are suitable for the coagulating bath.

After the gel has coagulated, it is drawn at a low draw ratio and then washed on a multiple-stage countercurrent machine to recover the solvent as a concentrated aqueous solution. A second draw of 400 – 600 % is carried out at boiling or intermediate temperature; the tow is then dried under tension. Annealing can be carried out during or after drying. The tow is then relaxed tension-free, oiled, cut into staple, and baled.

In wet processing, obtaining a homogeneous structure and avoiding discoloration and residual solvent are inherently difficult. The properties of the fibers are generally inferior to those produced by the dry process.

6.1.2. Fibers from Blends of Poly(vinyl chloride) Homopolymer

To avoid the inherent limitations of homopolymer fibers without loss of specific and outstanding properties, spinning blends of homopolymer and minor amounts of a polymer with fibrillar

structure to act as reinforcement has been proposed. Postchlorinated PVC (CPVC) or cellulose acetate [279] can be used without modification of the process. Other blends require special processes. Dry-spun fibers, which contain ca. 80 – 85 % PVC homopolymer and 15 – 20 % CPVC, exhibit the structure of a matrix reinforced with fibrils and have greatly improved heat dimensional stability, mechanical properties, and creep [280]. Such fibers are produced on a commercial scale by Rhône-Poulenc. If cellulose acetate or cellulose is used to replace CPVC, the level of heat stability increases [279], [281]. Researchers in the former Soviet Union proposed wet-spinning a blend of homopolymer with 4-phenylbenzimidazoterephthalamide in dimethylacetamide [282]. In all these cases, the PVC homopolymer is the matrix.

A Japanese firm (Kohjin Co.) produces a fiber (Cordelan) in which PVC and PVC – PVA [poly(vinyl alcohol)] graft-polymer particles are dispersed in a PVA matrix. This fiber gains heat dimensional stability, with concomitant reduction in chemical resistance, thermal insulation, and flame retardancy.

6.1.3. Products, Properties, and Uses

Products. Three major grades of products are available: (1) shrinkable products with different levels of shrinkage, (2) stabilized products for tow dyeing for apparel, and (3) highly stabilized products for piece dyeing and home furnishings (matrix-fibrils). Table 19 lists the physical characteristics of these grades. The stabilized grades are available in a wide range of fineness from 2.4 to 15 dtex and of cut lengths required for cotton, woolen, or worsted spinning systems.

Chlorofiber can be spun on cotton, woolen, or worsted systems as 100 % highly stabilized fiber or as blends of shrinkable and stabilized fibers. The fibers may be dyed at the boiling temperature or slightly below by use of selected disperse dyes. Only highly stabilized fibers can be yarn- or piece-dyed.

Properties and Related End Uses. The main end uses for chlorofibers are related to comfort, flame retardancy, chemical resistance, and surface processing.

Comfort. Chlorofibers exhibit high thermal and tactile comfort [283], [284]:

- high thermal resistance (0.23 – 0.25 m^2 °C $W^{-1}cm^{-1}$)
- constant thermal resistance with humidity transfer
- water transfer
- high rate of evaporation of perspiration
- feeling of warmth
- no lag time between sweat production and evaporative heat loss

Flame Retardancy. Chlorofibers have a very high level of flame retardancy as shown by the limiting oxygen index (LOI) of 46 % at 50 °C and 49 % at 150 °C. They do not ignite and spread flame, nor do they melt and form droplets in contrast to many other synthetic fibers. They may be blended with other flammable, staple fibers, such as wool and polyester, and retain their flame retardancy over a specific range of blend ratios. They can also be blended with thermally resistant fibers, such as aramid and preoxidized acrylic fiber, and exhibit outstanding heat resistance in terms of ignition temperature (640 – 680 °C) and ignition flux (6.4 W/cm^2).

Chemical Resistance. Homopolymer fibers withstand weathering and are resistant to most chemicals with the exception of polar organic compounds (chlorinated hydrocarbons, aromatic hydrocarbons, ketones, and a few others).

Surface processing. Woven or nonwoven fabrics of chlorofibers may be processed by thermal molding. Under the combined action of temperature and pressure, any shape can be achieved with a woven or knitted fabric composed of chlorofibers. These fibers may be heated and welded by high-frequency heating because of their low dielectric loss factor (0.013 at 50 Hz).

Trade Name, Producer (Plant Location): *Retractyl-Fivravyl, Thermovyl L9,* and *ZC,* Rhovyl (Tronville-en-barrois, France); *Teviron,* Teijin (Iwakuni, Japan); (Kustanai, former States of USSR); (Canton, Chunking, Foochow, Shanghai, Sengli, and Tientsin, all People's Republic of China).

Table 19. Physical properties of stabilized grades of PVC products

Property	Shrinkable fibers	Stabilized fibers	Highly stabilized fibers
Density, g/cm^3	1.4	1.38	1.38
Break strength, cN/dtex	2.5 – 3.0	1.6 – 2.2	2.1 – 2.5
Break elongation, %	15 – 20	85 – 105	45 – 55
Initial modulus, cN/dtex	30 – 40	10 – 11	12.5 – 13.5
Shrinkage in air, %			
at 100 °C	40 – 55	0.2	0
at 110 °C	45 – 65	15 – 25	5 – 10
at 115 °C	50 – 70	25 – 30	10 – 15
Temperature of maximum shrinkage stress, °C	80 – 100	135 – 140	135 – 140
Shrinkage stress, cN/dtex	0.04 – 0.06	0.02 – 0.03	0.015 – 0.02
Moisture regain (at 65 % R.H., 25 °C), %	0.05 – 0.1	0.05 – 0.1	0.05 – 0.1

6.2. Fibers from Postchlorinated Poly(vinyl chloride) (CPVC)

Poly(vinyl chloride) homopolymer (56.7 % chlorine) can be postchlorinated to a 73.2 % maximum chlorine content by free-radical chlorination. Solubility in common solvents, especially in acetone or blends containing acetone, depends on the chlorine content of different molecular chains and the distribution of blocks of poly(vinyl chloride) and 1,2-dichloroethane in each chain.

The *solution process* is believed to be the most suitable method of obtaining concentrated spinning solutions, with maximum solubility at a chlorine content of 63 %. Soviet (Chlorin) and German Democratic Republic (Piviacid) fiber producers claim a solution process using either tetrachloroethane or dichlorobenzene as solvent. The processing steps include solution preparation, chlorination, precipitation of polymer with nonsolvent, polymer washing, and solvent recovery [278].

The *quality specifications* of spinnable polymer are:

Chlorine content	63 – 65 wt %
Specific viscosity at 0.2 % in cyclohexane	0.2
Degree of polymerization	900 – 1000
Ash content	0.03 – 0.08 wt %
Iron content	1×10^{-3} wt %

Filament or staple fiber based on CPVC is spun by the dry or wet process in acetone. In wet spinning, the coagulation bath consists of water and a small amount of acetone; the spun gel is drawn 300 – 700 % in one or two steps.

The properties of the filament are as follows:

Linear mass	3.6 – 4.2 – 5.6 dtex
Break strength	>1.6 cN/dtex
Break elongation	>40 %
Density	1.44 g/cm^3
Shrinkage in boiling water	72 %
Limiting oxygen index	51.5 %

Fibers of CPVC have properties similar to homofibers, with slightly higher shrinkage and flame retardancy and lower chemical resistance and ease of dehydrochlorination [285].

Some attempts have been made to improve certain limiting characteristics: (1) grafting methyl methacrylate to increase moisture regain, (2) grafting acrylonitrile to improve thermal stability, and (3) blending CPVC with cellulose acetate at a ratio of 85 : 15 to increase the shrinkage temperature [278].

6.3. Fibers from Vinyl Chloride Copolymers

Copolymers of PVC with a 13 – 15 % vinyl acetate content and a vicosity index of 57 – 58 exhibit a lower glass transition temperature (73 °C) than homopolymers, and the bondability improves at temperatures lower than the melting point.

The process used is *dry spinning*. A solution of copolymer (≤50 wt %) in acetone, containing heat stabilizers and additives, is prepared at ambient temperature, filtered, and extruded at a temperature dependent on the polymer content (50 – 80 °C). A hot aqueous treatment without

tension, crimping, or oiling, and low-temperature drying follow if the fiber is to be used in the dry-laid nonwoven process; for the wet-laid nonwoven process, crimping is omitted.

The relevant key *properties* are:

Chlorine content	46 %
Break strength	0.6 – 0.7 cN/dtex
Break elongation	150 – 200 %
Softening point	69 °C
mp	155 – 160 °C
Decomposition temperature	230 °C
Shrinkage in water	18 – 28 % at 80 °C
Shrinkage tension	0.003 cN/dtex
Shrinkage temperature	60 °C

Bonding may be carried out between 80 and 150 °C or between 150 and 170 °C with transformation of the fiber into melt droplets. Thermal bonding is used to produce nonwovens, blended with other natural, regenerated, or synthetic fibers at a ca. 30 % maximum content.

Trade Name, Producer (Country): *Wacker MP-Faser,* Wacker Chemie (France); *Vinyon HH,* Celanese Co. (United States).

6.4. Fibers from Poly(vinylidene chloride) and Copolymers [278], [286], [287]

The homopolymer of PVDC has a softening point of 185 – 200 °C. Its two outstanding properties, high crystallinity and insolubility, make it difficult to process. Therefore, to ease processing conditions, copolymers with small quantities of vinyl chloride are used.

The usual copolymers contain 85 – 90 wt % vinylidene chloride (saran). Copolymers are processed by melt spinning or extrusion. Because they are heat sensitive and have a limited thermal life at the extrusion temperature, specially designed extruders and alloys are required. Depending on end use, plasticizers, heat and light stabilizers, and colored pigments may be added to the copolymer. Monofilaments or multifilaments are extruded at 160 – 175 °C, quenched in water at 10 – 15 °C with a short distance between the spinneret and the level of the quenching bath, and then drawn 500 – 600 %.

Products, Properties, and Uses. The range of *products* includes monofilaments (70 – 120 dtex) and multifilaments (10 – 78 dtex). Typical properties are:

Density	1.65 – 1.75 g/cm^3
Break strength	1.5 – 2.0 cN/dtex
Break elongation	15 – 25 %
Initial modulus	6 – 10 cN/dtex
Moisture regain	>0.1 %
Softening point	115 – 135 °C
mp	170 – 177 °C
Shrinkage temperature	70 °C
Dielectric constant at 60×10^6 Hz	3 – 5
Dielectric loss	tan δ 0.05

Poly(vinylidene) chloride has excellent resistance to acid, alkali (except ammonium hydroxide), and weathering but poor heat resistance. The products cannot be dyed easily; disperse dyes may be used but fastness is poor.

7. Poly(vinyl alcohol) Fibers

W. O. Hermann and W. Haenel applied for the first patent on poly(vinyl alcohol) [*9002-89-5*] (PVA) fiber in 1931. They reported that the fiber could be made from PVA by the well-known wet- and dry-spinning methods, and that the water resistance of the fiber could be improved by physical and chemical aftertreatment. However, they did not investigate further the production of a water-resistant textile fiber because their interest was limited mainly to the solubility of the fiber in water. Water-soluble PVA monofilament, made by dry spinning and called "Synthofil," was manufactured for a short time in Germany.

In 1940, I. Sakurada and his colleagues improved the hot-water resistance of wet-spun PVA fiber by heat-treating it in hot air and acetalizing it with formaldehyde; they developed the technology for production of a water-resistant textile fiber [288].

Wet-spun staple fiber based on this technology was first available commercially in Japan in 1950; the fiber was called "Vinylon." Initially, Vinylon was distinguished from other synthetic fibers by its hydrophilic properties and it was marketed as a substitute for cotton in both clothing and industrial fibers. Improved production technology led to remarkable improvement in the mechanical properties of the fiber. In 1959, high-tenacity filament produced by dry spinning, and later by wet spinning, became available. The use of Vinylon has become almost en-

tirely industrial. In addition to the water-resistant fiber, a water-sensitive variety has been produced for water-soluble fiber and binder fiber for making paper.

The staple fiber has been also produced commercially in the Democratic People's Republic of Korea since 1961 and the People's Republic of China since 1965.

7.1. Physical and Chemical Properties

The mechanical properties of commercial PVA fibers (Vinylon) produced in Japan are shown in Table 20 [289] (see → Fibers, 1. Survey, Chap. 5.). The tenacity and modulus are the highest among commercial general-purpose synthetic fibers. Fiber having a tenacity of 12 cN/dtex and a modulus of 274 cN/dtex has been produced for cement reinforcement. Resistance to abrasion and fatigue is also excellent. The fiber absorbs slightly more water than polyamide fiber; and its mechanical properties in the wet state are somewhat lower. Formalization is effective in improving water resistance of the fiber but may lower the mechanical properties. The elastic recovery is slightly lower than that of acrylic fiber but better than cotton or rayon. Acetalization with benzaldehyde is an effective technique for improving the elastic recovery of PVA fibers used in clothing. The resistance of PVA fiber to various chemicals is generally superior to that of polyamide and polyester fibers. In particular, its excellent alkali resistance is important in the reinforcement of cement products [290]. Because of its high polarity, PVA fiber adheres well to matrix materials in fiber-reinforced composites for resin, rubber, and cement. Its weather resistance is the highest of the various synthetic fibers.

The fiber is softened by heating above 230–240 °C, but it has no definite melting point. Commercial fibers with sufficient hot-water resistance, and water-soluble fibers that dissolve in 20–90 °C water, are produced by applying the appropriate heat or acetalization treatments. For use in wearing apparel, the formalized staple fiber, mainly blended with cotton, is dyed with direct, vat, sulfur, or metallized dyes.

7.2. Production

7.3. Poly(vinyl alcohol) for Fiber

Poly(vinyl alcohol) for fiber is produced by polymerization of vinyl acetate in methanol and subsequent alkaline hydrolysis of poly(vinyl acetate). The material must have a degree of polymerization of 1200–2500 and a narrow molecular mass distribution. These properties are attained by adjusting polymerization conditions, and especially by conducting the polymerization at a lower temperature and keeping the conversion of vinyl acetate in methanol below 70 %.

For the production of industrial fiber, PVA with a degree of polymerization of ca. 1700 is generally used. The amount of residual acetyl groups in PVA should be <0.1 mol % for heat treatment to produce a sufficiently water-resistant fiber.

7.3.1. Wet Spinning

Sodium Sulfate Coagulation Bath Method. Staple fiber and tow are produced by wet spinning.

In ordinary wet spinning, PVA is dissolved in water to a concentration of 14–16 % by heating. After filtration and deaeration, the spinning solution is kept above 70 °C to avoid gelation. It is extruded through spinnerets into a coagulation bath containing a saturated solution of sodium sulfate at 40–50 °C. The coagulation speed is much slower than that of viscose, and a longer residence time in the bath is necessary. For the coagulation operation to run smoothly, and to minimize floor space requirements, a vertical spinning machine is preferred [291]. The spun fiber tow is usually drawn while passing through a second hot coagulation bath and then dried.

The wet-spun and dried fiber is soluble in hot water. It is further drawn and heat-treated in hot air or by hot rollers at 210–240 °C. The temperature of the heat-treatment process must be higher than that of the hot drawing process. In heat treatment, a small amount of shrinkage is usually allowed in order to stabilize fiber structure. This treatment orients and crystallizes the polymer chains in the fiber, reducing the fiber solubility in hot water.

Table 20. Mechanical properties of Vinylon fibers [289]

Property	Staple and tow		Filament	
	Regular tenacity	High tenacity	Regular tenacity	High tenacity
Tenacity, cN/dtex				
Standard	3.5 – 5.7	6.0 – 9.3	2.6 – 3.5	5.3 – 10.6
Wet	2.8 – 4.6	4.7 – 7.9	1.9 – 2.8	4.4 – 9.3
Wet – standard ratio, %	72 – 85	78 – 85	70 – 80	75 – 90
Loop tenacity, cN/dtex	2.8 – 4.6	4.4 – 5.1	4.0 – 5.3	6.2 – 11.5
Knot tenacity, cN/dtex	2.1 – 3.5	4.0 – 4.6	1.9 – 2.6	2.4 – 4.4
Elongation, %				
Standard	12 – 26	9 – 17	17 – 22	6 – 22
Wet	12 – 26	9 – 17	17 – 25	8 – 26
Young's modulus, cN/dtex	22 – 62	62 – 221	53 – 79	62 – 221
Resilience at 3 % elongation, %	70 – 85	72 – 85	70 – 90	70 – 90
Relative density	1.26 – 1.30	1.26 – 1.30	1.26 – 1.30	1.26 – 1.30
Commercial regain, %	5.0	5.0	5.0	5.0
Water absorbency, %				
20 °C, 20 % R.H.	1.2 – 1.8	1.0 – 1.5	1.2 – 1.8	1.0 – 1.5
20 °C, 65 % R.H.	4.5 – 5.0	3.5 – 4.5	3.5 – 4.5	2.5 – 4.5
20 °C, 95 % R.H.	10.0 – 12.0	8.0 – 10.0	10.0 – 12.0	8.0 – 10.0

The heat-treated fiber is further acetalized in an aqueous solution containing 1 – 5 % formaldehyde, 10 –20 % sulfuric acid, and 5 – 20 % sodium sulfate at 50 – 80 °C for 10 – 60 min to reach a degree of formalization of 25 – 35 mol %. Acetalization is affected not only by reaction conditions but also by conditions of the drawing and heat-treatment processes applied to the fiber. Acetalization greatly improves the boiling-water resistance of the fiber and also changes its mechanical and chemical properties to some extent.

In the production of staple fiber, the heat-treated tow is usually crimped mechanically and cut, the cut fiber is formalized. For industrial application, the formalized tow is subjected directly to a stretch-break spinning system (Perlock or Converter system) to convert it to spun yarn. This yields spun yarn with high tenacity and high toughness.

Short-cut fiber, destined to be water-swellable binder fiber or water-resistant substrate fiber for making paper, is produced by cutting wet-spun and dried tow, or tow that has been heat-treated and sometimes formalized, to the proper length of 3 – 12 mm.

Alkaline Coagulation Bath Method. Fiber that has been wet-spun in a sodium sulfate coagulation bath has a cocoon-shaped cross section and skin – core of inhomogeneous structure because coagulation proceeds with rapid dehydration from the outside of the extruded jet of spinning dope. This makes it difficult to obtain a clear fiber with high tensile strength.

When PVA dope is spun into an aqueous solution of concentrated alkali, fiber with a round cross section and a homogeneous, compact structure can be obtained [292]. The fiber is transparent and can be highly drawn to give improved tensile strength and modulus, and better water resistance. In this case, the spinning dope extruded in the coagulation bath is gelated instantaneously by contact with the alkaline coagulant, so dehydration proceeds homogeneously. This wet-spinning method is used in Japan. In commercial practice, the aqueous coagulation bath contains sodium hydroxide at a concentration >200 g/L and at a temperature of 40 –50 °C.

The alkaline coagulation method was modified to give more highly drawn fiber with a higher modulus by using aqueous acidic spinning dope containing a small amount of boric acid [293]. Because of the presence of boron, cross-linking appears to occur between the polymer chains of PVA during fiber formation. This suppresses entangling of the polymer chains and makes coagulation more homogeneous.

The spinning dope, containing boric acid of 0.5 – 2.0 wt % (relative to PVA) at pH 3 – 5.5, is spun into an aqueous alkaline coagulation bath containing 20 – 100 g/L of sodium hydroxide and 100 – 300 g/L of sodium sulfate at pH 13.5 – 14.0. After removal from the coagula-

tion bath, the spun fibers are treated with acid, washed with water, dried, and drawn to a draw ratio >10 to give high tenacity (>9 cN/dtex) and high modulus (>177 cN/dtex).

This technology was developed initially for production of high-tenacity, high-modulus filament yarn for use in belt cord for radial tires. The yarn is modified further to produce high-modulus fiber, which can be substituted for asbestos in cement reinforcement; this fiber has a tenacity of 12 cN/dtex and a modulus of 274 cN/dtex [294].

Wet Spinning with Organic Solvent. Polyvinyl alcohol has a high crystalline modulus comparable to that of polyethylene. This high modulus has not been exploited extensively to date in the preparation of fiber. Various investigations have been carried out into the preparation of PVA fiber with a much higher modulus. In many cases, this has involved modified wet-spinning methods that use organic solvents.

When a hot, dilute solution of PVA in polyol is cooled slowly, highly crystallized PVA is deposited [295]. This phenomenon has been connected with gel-spinning – ultrahigh-drawing procedures. When the gel fiber from a solution of PVA in glycerin, having an ultra-high degree of polymerization of 38 000, was hot-drawn at high temperature, the resulting fiber had a tenacity of 17 cN/dtex and a modulus of 555 cN/dtex [296].

7.3.2. Dry Spinning

Dry spinning of PVA is used in the production of filament yarns. The two classifications of dry spinning are low-draft spinning [297] and high-draft spinning [298].

Low-Draft Spinning. Aqueous spinning dope, which has a concentration of 41 – 45 % and an extremely high viscosity, is used in low-draft spinning. It is prepared by dissolving PVA granules, conditioned with water, by heating them in an extruder under pressure.

The high-vicosity spinning dope at a temperature of 130 – 160 °C, is spun in air at ca. 50 °C. The cooled and solidified filament is wound in a low-draft ratio of 0.3 – 1.0 based on the extrusion rate of the spinning dope from the spinneret (i.e., draft ratio = winding rate/extrusion rate), and gradually dried while the drying temperature is raised. The dried filaments have a circular cross section, a homogeneous structure, and low strain; they can be drawn to the highest draw ratio and heat-treated near the melting point. The resulting filament has adequate hot-water resistance and is used commercially without formalization.

This method is suitable for producing heavier filament for industrial applications. It was originally developed for the production of heavier monofilaments of 110 – 1100 dtex. It is now also applied to the production of multifilaments, such as 1330 dtex/200 filaments.

High-Draft Spinning. In high-draft spinning, aqueous spinning dope containing PVA at a concentration of 28 – 41 % is spun at 90 – 95 °C into a spinning tube consisting of a drafting zone at 30 – 80 °C and 55 – 95 % R.H., and a drying zone at >80 °C and <50 % R.H. While passing through the spinning tube, the filament is highly drafted and dried so as to be taken off at a winding speed of 200 – 500 m/min. The dried filaments are hot-drawn and heat-treated, and sometimes further acetalized.

This method can give finer filaments (<5 dtex) for textile applications. Some filament for apparel, made from a mixture of PVA and aminoacetalized PVA is produced commercially and can be dyed with acid dyes. This method is now used primarily to produce water-soluble filament. Filament soluble in water at 20 – 90 °C is produced commercially by using PVA with low degrees of polymerization and saponification, and by adjusting heat-treatment conditions [299].

7.3.3. Mixed Spinning

The technology for spinning bicomponent fiber from PVA and poly(vinyl chloride) (PVC) in an emulsion was developed in 1961 [300].

Vinyl chloride is emulsion-polymerized in an aqueous solution of PVA, and the emulsion is mixed with PVA to give a spinning dope containing PVC and PVA in ca. 1 : 1 mass ratio. The fiber is produced in essentially the same way as regular PVA fiber, by using the sodium sulfate

coagulation bath method. The fiber is characterized by its flame retardance and is produced commercially in Japan under the name Polychlal.

7.4. Uses

In Japan, about 90 % of Vinylon fiber production, ca. 30 000 t/a, is consumed in industrial applications that require such advantages as high tenacity, excellent weather resistance, and effective reinforcing effect in matrices. The main industrial uses are fishing nets, ropes, belts, canvasses, and sewing threads. Perlock-type spun yarns from 100 % Vinylon tows and filament yarns are used predominantly. The water-soluble filaments are used to produce chemical lace fabrics.

The development of special grades has increased the demand for Vinylon remarkably. The water-swellable, short-cut fibers are popular as binders in the production of paper and wet-laid nonwoven fabrics. Another short-cut fiber, modified to have the highest tenacity and modulus as well as a special surface structure that enhances its adhesion to matrices, is used as a substitute for asbestos to reinforce cement products. These special grades are exported to the world market.

Only 10 % of Vinylon production is used domestically in Japan for apparel, mainly by blending Vinylon with cotton and other fibers. The main apparel application is work clothing that requires durability and chemical resistance.

In Korea and China, significant quantities of PVA fiber are blended with cotton and used for apparel. In these countries too, fiber applications in the future will shift gradually to industrial uses.

7.5. Economic Aspects

Poly(vinyl alcohol) fibers are produced in Japan, the Democratic People's Republic of Korea, and the People's Republic of China. In Japan, production levels reached a maximum of 76 000 t in 1971 and decreased to 36 000 t by 1984, while production capacity remained constant at 80 000 t/a [289]. Korea and China are presumed to have production capacities of more than 50 000 and 150 000 t/a, respectively.

The producers of Vinylon and Polychlal fibers in Japan, and their brand names, are as follows:

Vinylon:	Kuraray Co. (Kuraray Vinylon, Cremona,Kuralon), Unitika Chemical Co. (Unitika Vinylon, Mewlon), Nitivy Co. (Vilon, Solvron; water-soluble)
Polychlal:	Kohjin Co. (Cordelan)

8. Polytetrafluoroethylene Fibers

Polymerization technology for polytetrafluoroethylene [*9002-84-0*] (PTFE) has been known since 1941 and has become well established, leading to utilization of the polymer not only as a plastic but also in fiber form [301]. This is undoubtedly because it combines interesting chemical (inertness) and physical (low friction, temperature resistance, and triboelectric characteristics) properties.

Tetrafluoroethylene is polymerized under pressure in the presence of persulfate or peroxide in water; oxygen is excluded. The reaction is exothermic and increases in velocity with increased pressure. The viscosity of the polymer, as well as its molecular mass cannot be measured readily; however, indications are that the polymer chain is linear. At the normal polymerization level, molecular masses are estimated to be between a few hundred thousand and several million.

8.1. Physical and Chemical Properties

Some of the physical properties of polytetrafluoroethylene are as follows:

mp	327 °C
Glass transition temperature	ca. 120 °C
ϱ	2.1 g/cm^3
Melt viscosity (380 °C)	10 GPa

These fibers are similar to the polymer (i.e., highly crystalline 93 – 98 %) and, because of the high energy of the C–F bond, display appreciable resistance to heat and chemicals (see → Fibers, 1. Survey, Chap. 5.; → Fluoropolymers, Organic). As a result, the

polymer is difficult to burn. The fibers also are distinctive because of their good light and weathering durability, and their utility at temperatures up to 290 °C. Phase changes that occur below 30 °C are responsible for the cold flow characteristics of the material, although the fibers are reported to be more dimensionally stable than bulk polymer because of their molecular orientation. Decomposition products are generated above 290 °C at a rate of 0.0002 %/h. Copolymers, containing minor amounts of other fluorinated monomers, are also available. These are melt extrudable but, because of their high melt viscosities, only into monofils of ≥100 dtex. A 50 – 50 copolymer with ethylene (Tefzel, Du Pont) has a lower melt viscosity and can be extruded at commercially attractive speeds; however, its temperature–chemical characteristics are altered by the presence of the nonfluorinated comonomer.

8.2. Production

Polytetrafluoroethylene can be sintered above its melting point into a tough, viscous melt. However, melt spinning is not feasible with the homopolymer because the temperature required to overcome the viscosity leads to polymer degradation. Because economically attractive solvents for the polymer have not been found (a few fluorinated hydrocarbons dissolve several percent of polymer above 300 °C), either paste extrusion below the melting point of the polymer or dispersion spinning to form fibers is used. To promote agglomeration during extrusion of plasticized (with 20 wt % kerosene) homopolymer, extrusion is done under conditions favorable to production of particulates in ribbon form, so that at least 30 % have a width of 0.1 nm, an aspect ratio of at least 5 : 1, and a cross section of $<0.001\ nm^2$. Sintering, followed by drawing and heat-setting results in solid or expanded films (depending on process conditions), which are then split into filaments of ca. ≥100 dtex.

An alternate process is used to produce finer filaments. A 60 % solid dispersion of polytetrafluoroethylene polymer, stabilized with aryl or alkyl polyglycol ethers, is blended with viscose solution (5 %). The latter acts as a matrix during early phases of the process. The mixture is filtered and then extruded at room temperature through a multihole spinneret (hole diameter 0.15 mm) into a coagulating bath containing 6 % sulfuric acid, 16 % sodium sulfate, and 0.3 % zinc sulfate. The spinning velocity is about 12 m/min.

After coagulation, the yarn is washed with water at 90 °C, dried at 190 °C, and then raised to 340 – 360 °C, the temperature at which polymer particles are sintered and the viscose residue degrades and is partially burned. After a brief contact time at 360 – 390 °C, the yarn is stretched four to eight times its original length.

The resultant continuous-filament yarn has a tenacity of 1.8 cN/dtex and an elongation of 20 – 30 %. The filament mass is 6 dtex. The fibers are brown and can be bleached in boiling sulfuric acid containing nitric acid or by exposure for several days in an air oven. The latter must be done cautiously by raising the temperature stepwise to 350 °C, to avoid exotherms because of the sudden oxidation of the viscose residues.

8.3. Uses

Polytetrafluoroethylene fibers are utilized in woven and nonwoven forms as filter media for aggressive liquids and gases (i.e., strong acids, bases, and oxidizing agents), including air pollution control fabrics. Fibers are also used in gaskets and pump seals because of their chemical resistance and low-friction characteristics. In electrical systems, they are utilized as insulators for wires and components, and as cleaners – wipers in xerographic devices, where their high-temperature and triboelectric characteristics are important. Because of their great chemical stability, these fibers are used as the binder component in asbestos chlor-alkali cell diaphragms. The low-friction characteristics and high length – diameter ratio of the fibers are important in their use as solid lubricants in engineering plastics. Monofils have found application in demisters in the production of mineral acids.

In addition, dispersion of fibers on woven or nonwoven substrates imparts chemical stability to the surface and results in layered composites with excellent dielectric properties and corrosion resistance for utilization in xerography.

Trade Names. Teflon [*98846-34-5*], Teflon FEP [*58516-09-9*], Teflon TFE, Teflon PFA

[*71767-39-0*], Tefzel [*25038-71-5*], Tefaire (Du Pont, United States); Goretex (Gore, United States); Polyflon (Daikin Kogyo, Japan); Toyoflon (Toyo Rayon, Japan); Fluon (ICI, Great Britain).

8.4. Toxicology and Occupational Health

Adequate ventilation should be provided during processing of PTFE fibers. At elevated processing temperatures, PTFE fluoropolymer fibers liberate vapors that may be harmful. Generally, adequate ventilation and care to prevent such vapors from being inhaled will provide ample safety. Care should be exercised not to contaminate smoking tobacco with PTFE fibers. A mixture of tobacco and PTFE polymer would be especially hazardous if the mixture were combusted and inhaled in smoking. This can be avoided by not carrying tobacco into areas where it may become contaminated.

1. Survey

1.1. General Description of Inorganic Fibers

The inorganic fibers are treated in five chapters: Glass Fibers, Refractory Fibers, Metal Fibers, Carbon Fibers and Refractory Ceramic Fibers.

In this introduction, the similarities with organic synthetic fibers, as well as special characteristics, are treated generally.

Unlike organic fibers, there are no natural sources for inorganic fibers, with one exception, asbestos fibers, which are a separate keyword (→Asbestos). As synthetic products, inorganic fibers have obvious similarities with the synthetic organic fibers, first of all in the morphology and terminology of the commercially available forms and in their field of technical application. Synthetic organic (Chardonnet silk, a regenerated cellulose fiber (see Fibers, 1. Survey) and inorganic fibers were first fabricated a hundred years ago. The critical difference between inorganic and organic fibers is seen in the differing properties, which correspond in general to those of organic polymers on the one hand and to those of inorganic and metallic materials on the other hand.

Nonmetallic inorganic fibers are stronger, stiffer, higher melting, and thus more heat resistant, and in all cases nonflammable, but, except for metal fibers, they are also characterized by brittleness. Based on these general properties, they are less important as textiles per se; however, they are superb for reinforcement of other materials, in the so-called composites (→Composite Materials).

They are excellent as thermal insulation at high temperatures and in corrosive environments.

1.1.1. Commercial Forms and Terminology

The term *fiber* can be used for a formed material that has a length-to-diameter ratio of at least 10 : 1, and with a cross-sectional area below 0.005 mm^2 and a thickness below 0.25 mm [1]. This standardized nomenclature also includes *whiskers*, which are mainly single-crystal materials, and are treated under a separate keyword (→Whiskers). Nonmetallic fibers include both continuous (endless) and short fibers. Diameters range between 5 and 15 µm, but some are much thicker, for instance, the fibers made by chemical vapor deposition on a substrate fiber such as B or SiC fibers which have diameters of ca. 100 – 150 µm. The diameter is of critical importance in regard to the tensile strength, because all materials showing brittle fracture increase in strength as the diameter decreases (Fig. 1).

Figure 1. Tensile strength of monofilaments (carbon fibers) as a function of fiber diameter. a) Hercules AS4 (Hercules); b) Torayca T300 (Toray); c) Torayca M40 (Toray)

Short fibers can be fabricated by a melt spinning process directly to staple fibers (see pp. 16 and 23 – 24) or by chopping (cutting) of continuous fibers. Commercial short-fiber products include wool, mats, and felts. The spinning of short fibers to continuous yarn, as with natural organic fibers, is generally not practiced for synthetic inorganic fibers.

Continuous fibers are fabricated by melt spinning, if the fiber materials are meltable, such as is the case for glass or mineral fibers. The advanced inorganic fibers, such as carbon fibers and also those of refractory ceramics, are made from organic precursor fibers via thermal degradation. For the spinning of the precursors the methods for fabrication of synthetic organic fibers are used. This precursor technique can produce both monofilaments and multifilaments, as described in "Organic Fibers" (Fibers, 4. Synthetic Organic). Only filament yarns which consist of up to 300 000 filaments are commercially available (see "multifilament tow" in Chap. 5.6.2). For reinforcement in advanced composites, tows of 3000 to 12 000 monofilaments (3 – 12 K tows) are used.

Meltspun glass fibers are also fabricated as filament tow and applied in rowings of some thousands of monofilaments. The terms *rovings* and *tows* are synonymous for filament yarn. Fabrics from filament yarns are commercially available. They are fabricated by weaving, braising, or similar techniques without binder to textiles, tubes, filter sieves, cables, etc. The chemical vapor deposition (CVD) method of fabrication, a method developed to produce boron fibers and still used for B and SiC fibers, can only be used to produce monofilament fibers. Such monofilament fibers are used to reinforce polymers, although of decreasing importance. However, such fibers may be useful in the reinforcement of light metals. The CVD technique can be used with success to fabricate yarns of high-melting substrate fibers with a coating on the individual monofilament, e.g., SiC or B_4C on boron or TiN, SiC, etc. on carbon.

1.2. Crystalline Structure and Mechanical Properties

Glass and mineral fibers are characterized by their amorphous structural state, while metal and some oxide fibers such as the DuPont A1203 fiber are characterized by their polycrystallinity.

In the case of most refractory ceramics produced from organic precursors, and also in the case of carbon fibers, the structure is not fully amorphous, but the crystals in the fibers are so imperfect that the term polycrystallinity can be used only with reservation. As a consequence, postheat-treatment of such fibers above 1000 °C easily initiates crystallization processes as demonstrated on quite pure Si_3N_4 fiber (experimental-type Tonen in 1988, [2]) in Figure 2. The room temperature strength of the fabricated fiber with final pyrolysis temperatures of 1000 °C in nitrogen is 2450 MPa, an impressive value, but after heat treatment at

Figure 2. Composition and X-ray diffraction of an experimental-type silicon nitride fiber with the composition in mass fraction: 59.2 % Si, 39.1 % N, 0.5 % C, 1.1 % O, 0.1 % H; θ = Bragg angle [2]

1600 °C, a perfect β-Si_3N_4 crystal structure develops, and room-temperature strength drops below 1000 MPa, a considerable lowering of the mechanical properties. Figure 3 shows further examples where the decrease in strength due to thermally activated crystallization is even more extreme.

Figure 3. Decrease of tensile strength of various inorganic fibers made by the precursor method (room temperature tensile strength) HTT = heat treatment temperature

The well-known strength decrease of glass fibers at elevated temperatures is caused by facilitated flow processes because of lowered viscosity (Fig. 4).

	E-Glass	R-Glass
SiO_2	53-54%	60%
Al_2O_3	14-15%	25%
CaO	20-24%	6%
MgO		9%
B_2O_3	6-9%	
α [K^{-1}]	5×10^{-6}	4×10^{-6}
EP	840°C	990°C

Figure 4. Decrease in tensile strength and composition of glass fibers at elevated test temperatures

The drop in strength by postheat-treatment is also observed for carbon fibers and explained by thermal healing of structural defects within the polyaromatic layers, thus breaking cross-linkages between them. This healing process enormously increases the tensile modulus of the fibers because of the extreme anisotropy of the graphite-like carbon structure. In no case can three-dimensional crystallinity, as in the graphite structure, be achieved by postheat-treatment of carbon fibers, not even above 2700 °C. Therefore, carbon fibers never consist of polycrystalline graphite and the term "graphite fibers," as used commercially in the United States, is scientifically unjustified and misleading.

A characteristic of inorganic fibers, whether amorphous or polycrystalline is that they all exhibit brittle fracture without plastic deformation. Figure 5 shows some examples. Only metallic fibers behave differently.

Figure 5. Stress – strain diagram of some inorganic fibers

The strain-to-failure (elongation at fracture) for the brittle fibers follows precisely the ratio strength to tensile modulus. This explains why high-modulus inorganic fibers show the lowest values of strain to failure, values below 0.5 %. For reinforcement of polymers, as in advanced composites, an elongation up to 2 % is required by aircraft designers. This requirement is met by the low-modulus glass fibers but not by the advanced carbon and ceramic fibers. Glass fibers, therefore, are privileged in engineering application if fracture toughness and impact resistance are required without the need for extreme stiffness. If high tensile moduli have to be maintained, the elongation can be improved only by increasing the fiber strength (Fig. 5).

It has been well known since GRIFFITH that the fracture in brittle materials is initiated by tensile stresses far below the intrinsic strength of the material due to notches of a minimum – the so-called critical length [3]:

$$\sigma = \sqrt{\frac{E \cdot \gamma}{C}}$$

The probability for the presence of such a notch decreases with decreasing volume of the tested sample. For fibers having the same diameter, the measured values for the tensile strength increase with shorter gauge length and if the same testing length is used, with smaller diameter of the same fiber type. Figure 1 shows the tensile strengths of monofilaments of commercial fibers as a function of the fiber diameter.

As a consequence, the efforts to develop new high strength inorganic fibers for reinforcement are directed to smaller diameter filaments, for instance 5 µm. However, this way to improve strength and elongation is limited by the danger of carcinogenicity of all fiber materials thinner than 3 µm that have length to diameter ratio larger than 3 ($l/d > 3$)

if the fiber material is persistent *in vivo*. A hypothesis concerning cancerogenic potency on geometric parameters was published in 1978 (Fig. 6) [4].

Figure 6. Carcinogenicity of thin inorganic fibers [4]

As a further consequence, the testing method, especially the gauge length of the fiber to be tested for tensile strength, has to be strictly standardized.

1.3. Testing Methods for Inorganic Fibers

Inorganic fibers are characterized mainly by tensile strength. Longfibers, at least 30 mm in length, are tested as monofilaments in a paper frame as demonstrated in Figure 7. Each commercial testing machine can be used for this purpose. A gauge length of 25 mm is the standard [5]. The critical problem is the determination of the monofilament cross section. In the case of circular morphology, the measurement of the monofilament diameter by a scanning microscope gives reproducible results. The diameters of the monofilaments in a bundle can vary ± 10 % [6]. If the fibers have irregular morphology, only integration of the cross sectional areas of the monofilaments in samples cut perpendicularly to the fiber axis using optical or electronic microscopy comes into question. Figure 8

The only commercial method is the strand method [7].

Figure 7. Paper frame method for testing room temperature tensile strength of thin monofilaments

Figure 8. Distribution of tensile strength of monofilaments of a carbon fiber tow [6]

The cross section of the bundle may also be determined by the mass per length of the tow and by the pycnometer density or alternatively by the He density of the fiber material. The precondition for this cross section determination is a circular morphology.

The term "dtex" (1 tex = 1 g per 1000 m) is used to characterize the mass of a filament fiber; this is the same as for synthetic organic fibers (→ Fibers, 4. Synthetic Organic).

A special test is the *loop test*, which is applicable for thicker monofilaments (see Fig. 9). This test can be modified to the *knot test* for fast qualitative characterization of the flexibility of filament fibers.

Figure 9. Loop test for low modulus A) and high modulus B) monofilaments indicating flexibility of inorganic fibers

$$D_{\text{loop}} \sim \left(\frac{d}{\varepsilon}\right)_{\text{fiber}} = \left(\frac{d \cdot E}{\sigma}\right)_{\text{fiber}}$$

D = loop diameter, d = fiber diameter, ε = fiber elongation, E = fiber modulus, σ = fiber strength

The tensile modulus is measured during the tensile strength test or nondestructively by the *ultrasonic method*, which gives good comparative results.

The compressive strength of the various inorganic fibers is a further characteristic property, but can only be measured if the fibers are inbedded in a unidirectional composite with a resin as matrix and a fiber volume fraction of 60 %. Isotropic fibers have high compressive strength, but the fibers with anisotropic structure and high preferred orientation parallel with the fiber axis show lower compressive strengths. The worst compressive strengths appear for the ultra-high-modulus types; here, the mesophase pitch-based carbon fibers are surpassed in a negative sense by the high-modulus organic fibers.

The determination of the linear thermal expansion of fibers is straight-forward; however, the determination in the perpendicular direction is extremely difficult. For carbon fibers this is important because of the high degree of anisotropy and the variety of degrees in preferred orientation. Data from direct optical measurements are compiled in Table 1. An indirect method is the comparative dilatation measurement using the pure resin and the fiber-reinforced composite.

Table 1. Thermal expansion of inorganic fibers

Oxide fibers	7.0 – 8.6	7.0 – 8.6

* parallel (||) or perpendicular (⊥) to the fiber axis

1.4. Inorganic Fibers for Thermal Insulation

The use of inorganic fibers for insulation is based not only on the low thermal conductivity of the material itself (one to two orders of magnitude less than that of metals) but also on the large volume between the fibers. These two aspects are discussed in detail in the chapter 2. Application of glass fibers is limited as shown in Table 13, but refractory oxide fibers allow use at much higher temperatures. Saffil fibers Al_2O_3 and ZrO_2 wool from ICI are examples (see Section 3.2.4). Upper application temperature is ca. 1650 °C. Even carbon felt can be used as thermal insulation; in

Table 2. Thermal conductivity of insulation layers from inorganic fibers

	Measured at °C	in W/mK

	1650	0.23
Carbon-Felt (Sigri)		
HTT = 1000 °C	20	0.06
HTT = 2000 °C	20	0.08

For comparison thermal conductivity of various materials, measured at room-temperature in W/mK

Cu	Al	Steel	C-Fiber	Glass	Polyethylene
370	175	46	12 – 23	0.9	0.23

Effect of insulation layers

Type	Thickness	Hotface	Coldface
Mullite	1 layer (ca. 3 mm)	1000 °C	500 °C
(in air)	3 layers (ca. 9 mm)	1000 °C	300 °C
Carbon Felt	40 mm	1600 °C	360 °C
(in argon)	40 mm	1200 °C	260 °C

spite of the high thermal conductivity characteristic of all carbon materials, the upper application temperature in a non-oxidizing environment is 2000 °C (see Table 2).

Mostly short fibers, such as wools, felts, textiles, and similar fabrics, are used. Mechanical properties and variation in individual fiber thickness is of little importance.

1.5. Inorganic Fibers for Reinforcement Purposes

1.5.1. Principles of the Fiber Reinforcement

Controlled inclusion of fibers into a homogeneous matrix produces a fiber-reinforced composite. The properties of the composite can be precalculated from the properties of the tow components, their volume fractions, and the geometrical arrangement of the fibers within the isotropic matrix. The simplest case is the unidirectional (UD) reinforcement with continuous fibers, where the rule of mixtures can be applied (Fig. 10A). Comparison of the precalculated and actual composite properties reveals the efficiency of the translation of the fiber properties into the composite. With good adhesion between fibers and matrix, efficiencies of 80 – 100 % can be achieved, especially as far as the moduli are concerned. Exact precalculations are described in [8] and elsewhere.

Figure 10 (see next page). Principles of reinforcement in unidirectional composites
A) Rule of mixture for strength data in fiber direction E_c = Young's modulus of composite, $E_{F,M}$ = Young's modulus of fiber and matrix, $x_{F,M}$ = Volume fraction of fiber and matrix, η_E = Yield of fiber modulus in the composite, a) Fiber; b) Composite; c) Matrix
B) Angle dependence of strength a) in unidirectional long fiber reinforced composites and b) in isotropic short fiber composites [9]
C) Stiffening effect by short carbon fibers in aluminum and thermoplastics a) C-Fiber/Thermoplastics; b) C-Fiber/Aluminum

Estimation of the strengths by precalculation, even in unidirectional reinforced samples, is more difficult, because the fracture processes overlap with the reinforcement effect. If we consider a polymer matrix with strain-to-failure exceeding that of the fibers, which is generally the case, the crack starts in the fibers. The degree of adhesion between fibers and matrix and the nature of the interphase contribute to the extent of the reinforcement effect. In addition, chemical and physical compatibility must be considered. Nevertheless, the simple rule of mixtures is still useful and reasonably valid.

The precalculated reinforcement for UD composites is achieved only in the fiber direction. For other directions, reinforcement is less effective. The strength of a UD composite across the fiber axis is that of the pure polymer (Fig. 10B) [9].

Short fibers arranged statistically in all directions, produce reinforcement of 1/6 of that precalculated for UD composites by the rule of mixtures, but this strengthening is isotropic. However, it should be demonstrated in each case whether or not reinforcement is worthwhile for a specific material combination. For example, as shown in Figure 10C, addition of short carbon fibers to an aluminum matrix is not effective [10]. Precise stiffness and strength information is a prerequisite for the successful design of fiber-reinforced matrices.

1.5.2. Commercial Continuous Inorganic Fibers

Mechanical Properties For a better understanding of the character, properties, and the importance of today's inorganic fibers and future trends, a brief history is helpful. The fiber reinforcement of polymers started during the 1930s but was not commercially successful until the 1940s, only after the interface problem had been solved by means of coupling agents. In the 1950s the U.S. Air Force and later the NASA supported development of reinforcing fibers to achieve light weight and high stiffness for future airplanes. Boron, a light but high-melting element, was selected as the most promising candidate. A new production technology was developed: *chemical vapor deposition* on thin tungsten wires. The boron fibers fabricated in this way are monofilaments with diameters between 120 and 150 µm and have more the character of thin wires than that of fibers. Therefore chemists started to develop filament fibers from the neighboring element carbon, which is also light and has a high melting point, and from which fibers have been demonstrated 100 years earlier as fila-

Table 3. Mechanical and physical properties of the representative inorganic fibers

Fiber type	Room temperature properties		
	Density, g/cm^3	Tensile strength, MPa	Tensile modulus, GPa
Glass fiber	2.50 – 2.62	3400 – 4500	70
Carbon fiber	1.76 – 2.10	2000 – 7000	240 – 700
CVD ∗ Monofilaments			
SiC fibers	2.55 – 3.50	2000 – 3700	200 – 420
Oxide fibers (whisker)	3.90	1200 – 1400	340 – 400

∗ CVD = chemical vapor deposition

ments for electric light bulbs. The high stiffness was achieved by hot working, similar to the processing of metal wires. Real technical success was achieved, however, only after this high-temperature forming process became superfluous upon introduction of the preferred orientation in the process step before thermal decomposition of the polymer fiber to the carbon fiber. These carbon fibers, which can be handled like glass fibers, have completely replaced boron fibers in their function of stiffening polymer composites. They are widely used today in combination with glass fibers in so-called advanced hybrid composites. Boron fibers on wire substrates have also been used to reinforce light metals. But in this field, too, a new competitor has appeared, namely, CVD-SiC fibers, thick monofilaments, much like thin wires. Silicon carbide is oxidation resistant in air up to 1400 °C, but has a density of 3.5. It is heavier than the light metals or boron. It is a superior fiber component in SiC and Si_3N_4 ceramics, especially for toughening. The troublesome CVD technique and the sticking of the monofilaments, both dangerous for the workers, have led to the development of a new competitor, SiC and Si_3N_4 filament yarns, which are fabricated much like carbon fibers by thermal degradation of polymeric precursor fibers, carbosilanes, and silazanes. For oxide composites, refractory oxide fibers are best. Fabrication techniques starting from organometallic precursor fibers as shown above, have so far produced only low-strength fibers, but improvement can be expected. Fabrication from ultrafine crystalline powder produces higher strength fibers [11].

Commercially available today are glass fibers, carbon fibers (HT and HM types), CVD boron, SiC monofilaments, SiC and Si_3N_4 fibers, and Al_2O_3 fibers. The physical and mechanical properties are compiled in Table 3. The specific strengths and tensile moduli are presented in a more schematic way in Fig. 11 [12]. All mechanical properties are determined at room temperature and under standard conditions. Composites with these stiffnesses are brittle, however. The impact resistance of the various fibers is therefore an important criterion for their application. Carbon fibers behave worst in this respect in spite of the other overwhelmingly excellent properties, as shown in Table 4 (see next page). One way to overcome this brittleness is to mix the carbon fibers with glass fibers (Fig. 12). Organic polyaramide fibers (Kevlar from DuPont or Twaron from ENKA) are included in Table 4 and Figure 12 to allow comparison.

Figure 11. Mechanical room temperature properties of inorganic fibers in a stress – modulus diagram [12]

1.5.3. Surface Chemistry, Surface Treatment, and Surface Properties

All commercial inorganic fibers are sized, i.e., coated with a thin organic, usually polymeric, layer to protect the fiber surface and to improve the handling of the brittle fiber material. The most common sizing materials are poly(vinyl alcohol) and uncured epoxy or polyimide resins. Glass fibers are coated by coupling agents, usually silanes, to improve adhesion in the matrix resins, which are usually unsaturated polyesters and, in advanced composites, epoxy resins. Glass fibers have silanol groups on the surface, which can react easily with functional groups in the resin. As such, interfaces within the composites are very sensitive to attack by water, and the glass fibers must be protected by linear organic molecules that have a hydrophobic group on one end of the molecule. The mechanism of protection is indicated in Figure 13 [13].

Carbon fibers are thoroughly wetted by the various polymers if they possess such functional surface groups as acid and basic surface oxides [14]. Also, the adhesion in the composite is explained by chemical interchange with these sur-

Figure 13. The effect of coupling agents for glass fibers in polymers (schematic) [13]

face groups. The surface oxides are formed on the carbon fibers as the last step during fabrication. All commercial carbon fibers are surface-treated and sized in this way. The process parameters of the surface treatment strongly influence the degree of surface oxidation, and thus the character of the interfaces within the composite. Surface treatment is, however, usually a proprietary process kept secret by the supplier. The suitability of the commercially surface treated and sized fibers must be tested and confirmed by the user.

Adhesion between fiber and matrix plays an important role in respect to the impact resistance of the composite. Dependant on the strain-to-failure of the fiber, impact resistance can be improved or worsened by a high degree of adhesion, which in turn is determined by the degree of surface oxidation [15]; Figure 14 shows some correlations.

Figure 14. Impact strength of carbon fiber-reinforced unidirectional composites as a function of fiber strain for the untreated and surface-treated state
U: Untreated; S: Surface treated

The chemical compatibility with the matrix is another criteria for inorganic reinforcement fibers. Glass fibers are compatible with polymers, with most oxides, but not with concrete. Carbon fibers are also compatible with polymers, and in addition they are compatible with concrete. They are not compatible with most metals, with the exception of lead and tin. They are incompatible with oxides above 400 °C. Surface coatings as diffusion barriers improve the chemical compatibility. Boron fibers are compatible with polymers, but react with metals. Even in the case of reinforcement of aluminum, boron fibers must be coated by diffusion barriers, thin layers of SiC or B_4C deposited from the vapor as the last step of the fabrication process (Fig. 15) [16, 17]. SiC fibers are compatible with polymers, and generally with most inorganic materials, if 1000 °C is not exceeded. Refractory oxide fibers would be ideally suitable for combination with light metals if properties and economic considerations justify it.

Figure 15. Boron fiber fabrication on tungsten substrate by the CVD process (chemical vapor deposition) [16]

1.5.4. High-Temperature Behavior of Inorganic Fibers

Glass fibers are limited to temperatures below ca. 300 °C. Carbon fibers are not resistant to oxidation above 400 °C, but are thermally stable up to 2000 °C in non-oxidative environments. They can be applied in all high-temperature polymers without restriction. For the highest temperatures, the performance of PAN-based carbon HM-fiber must be considered as exemplary. They can be used in composites with

carbon as matrix without limitation (carbon–carbon composites [18]), but diffusion barriers are needed in the cases of matrices of oxides, metals, and non-oxidic refractory compounds [19]. Some examples are given in Figures 16, 17, and 18 [20]. All other refractory fibers lose their room-temperature strength values if heat-treated above 1200 °C because of crystallization processes (see Figs. 3 and 4). Inorganic fibers resistant to high temperatures are a fertile field for further development.

2. Glass Fibers

2.1. Textile Glass Fibers

Textile glass fibers have gained in importance in spite of the availability of other, newer reinforcing fibers, such as carbon or aramid fibers [21–25]. A large part of this growth is a result of glass fiber-reinforced plastics (GRP). The market for GRP in the Federal Republic of Germany has grown from ca. 10 000 t in 1960 to ca. 200 000 t in 1985.

Glass fibers that can be processed by conventional textile techniques such as weaving are called textile glass fibers, to contrast them with insulation glass fibers. Textile glass fiber is a collective term for fine fibers possessing an approximately uniform, mostly circular cross section made from molten glass. The terminology of textile glass and processing aids is standardized in national and international standards.

Depending on the manufacturing process, textile glass fibers are subdivided into (1) glass filaments and (2) glass staple fibers, which are defined as follows in ISO 6355:

1) A glass filament is a textile glass fiber of practically unlimited length of a given diameter drawn from molten glass.
2) A glass staple fiber is a textile fiber of limited length (spun fiber) and of a given diameter.

Textile glass is used both for textile purposes, e.g., decoration, insulation, filtration, as well as for reinforcement of a matrix to form a composite. Matrices can be plastics (both thermosetting and thermoplastic), bitumen, rubber, cement, gypsum, or other materials. Of all glass filaments ca. 90 % are used to reinforce a matrix.

Textile glass fibers can also be categorized by the type of products and the diameter of the filaments:

1) Textile products, such as textile glass yarns and plied yarns with filament diameters of 5 – 13 µm
2) Plastic products such as mats, rovings, chopped strands, and milled fibers with filament diameters of 9 – 24 µm

The textile products are mostly woven and are then available as fabrics for reinforcing plastics

Figure 18. Toughening of alumina by silicon carbide coated carbon fibers a) Uncoated C-Fibers; b) SiC-Coated C-Fibers

and other applications such as thermal insulation and decoration.

Plastic products can be manufactured to parts by hand lay-up, winding, molding, etc. (Chapter 4).

History. The technique of ornamenting glass vessels with glass yarns was used in ancient Egypt around 1600 B.C. and developed further by the Romans. In the Middle Ages, this technique–based on drawing heated rods into fine filaments–was further refined in Venice and Murano.

The first indications of the use of glass yarns in fabrics are found in the work of the physicist FERCHAULT DE REAUMUR in 1713. The first known factory for the manufacture of glass yarns was founded in 1866 in Vienna by JULES DE BRUNFAUT. The inventor of the bushing, however, was LOUIS SCHWABE, who first produced glass yarns by drawing the melt through fine holes. In 1908, a rather coarse, endless glass fiber was demonstrated in Hamburg by W. V. PACZINSKY. True industrial production of textile glass fibers was realized in the United States in 1930 and in Germany in 1939.

2.1.1. Chemical Composition and Properties

Chemical Composition. The chemical composition of glass fibers essentially determines the properties and the applications. Table 5 shows the known types of textile glass fibers and their compositions.

Table 5. Chemical composition of textile glass (nominal values, wt %)

Component	Types of glass								
	Multi-purpose	Acid resistant			Alkali resistant	High strength		Good dielectric properties	
	E	A	C	E-CR	[31]	R	S	D	Quartz
SiO_2	53–55	70–72	60–65	58	60	60	60–65	73–74	100
Al_2O_3	14–15.5	0–2.5	2–6	12–13	0.7	25	20–25		
CaO	20–25	5–9	14	21	5	6		0.5–0.6	
MgO	20–25	1–4	1–3	4.5		9	10		
B_2O_3	6.5–9	0–0.5	2–7	<0.1			0–1.2	22–23	
F	0–0.7			<0.15					
Na_2O	≤1	12–15	8–10	0.6	14		0–1.1	1.3	
ZrO_2	≤1				18				
K_2O	≤1	1		0.4				1.5	
Fe_2O_3	≤1			0.3	0.1				
TiO_2	≤1			2.1					

The following types are recognized:

E glass. An alumino-borosilicate glass with a mass fraction of alkali ≤ 1 %, which is generally used in glass-reinforced plastics and in electrical applications

A glass. An alkali-lime glass with little or no addition of boron trioxide and a mass fraction of alkali ≥ 1 %, for special applications

E-CR glass. An alumino-lime silicate glass with a mass fraction of alkali ≤ 1 %, especially suited for the reinforcement of plastics because of acid resistance

C glass. An alkali-lime glass with high boron trioxide content, with good chemical resistance for special applications

D glass. A borosilicate glass, a specialty glass with high dielectric properties

R glass. An aluminosilicate glass without added calcium and magnesium oxides, glass that meets high mechanical requirements

S glass. An aluminosilicate glass without added calcium oxide but with a mass fraction of magnesium oxide of ca. 10 %

The most widely used are E-glass fibers, which are encountered in all areas of industry and everyday life, especially in combination with plastics (Chapter 4). In glass staple fibers, C glass is used primarily [29].

More recently, acid-resistant E-CR-glass fibers have been used in special projects such as pipes for flue-gas desulfurization plants. Alkali-resistant glass fibers are primarily intended for cement reinforcement.

High-strength textile glass fibers such as R- and S-glass fibers are preferred in applications where high tensile strength is needed, e.g., in containers under high internal pressure.

The raw materials for the components are largely natural minerals. They are subject to stringent quality control when received, since the raw materials must be within narrow, well-defined limits to produce textile glass fibers having uniform properties.

Properties. Textile glass fibers are distinguished by particularly high tensile strengths. Measurements on filaments drawn directly from the bushing yield values of 3400 MPa for E glass and 4400 MPa for R glass (Table 6).

The modulus of elasticity, which is 1/3 that of steel and quite adequate for many applications, and the density of 2.6 g/cm^3, which is high compared to plastics, are not sufficient for large-surface, light-weight parts (airplane construction). For such parts, fibers of lower density and higher modulus of elasticity (aramid and carbon fibers) were developed.

Textile glass fibers have a linear stress – strain curve up to the break, so that the break elongations ε_B can be calculated from the modulus of elasticity E and the tensile strengths σ_B (Fig. 19, see next page). Good resistance to weathering and heat, nonflammability, good dielectric properties, low thermal expansion, and, depending on the type of textile glass, good resistance to corrosion, are additional characteristics of textile glass fibers. The thermal conductivity of textile glass products is determined by the density of fiber packing. The properties of textile glass fibers to a great extent determine the properties of the composites (→Composite Materials).

Table 6. Properties of textile glass (nominal values)

Property	Types of glass								
	Multi-purpose	Acid resistant			Alkali resistant	High strength		Good dielectric properties	
	E	A	C	E-CR	[31]	R	S	D	Quartz
Density, g/cm^3

Freshly drawn fiber	3 400	3 100	3 100	3 330	3 700	4 400	4 590	2 500	400 – 500
Fiber in composite	2 500		2 400			3 750		1 550	
Dielectric constant at 1 MHz	5.8 – 6.4		6.8	7		5.6 – 6.2	4.9 – 5.3	3.85	3.78

2.1.2. Manufacture

2.1.2.1. Glass Filaments

Glass filaments are produced continuously by the bushing fiberizing process. There are two commercial processes for the manufacture of glass filaments: the marble melting process and the direct melt process.

In the older indirect *marble melting process,* the production of glass and the glass spinning process are separate. E glass is initially produced in the form of glass marbles (15 – 20 mm diameter), which are then re-melted in a second phase in the glass forming process (two-stage process). This process is still in use today for making fine filament yarns.

In the *direct melt process,* molten glass flows directly from the melting furnace into a system of heated feeders (channels) in which the bushings are placed. In this one-step process, there is no separation between glass manufacture and glass forming (Fig. 20). Temperatures in the pro-

Figure 19. Stress – strain curves of five fibers

duction of E glass are 1310 – 1390 °C in the furnace and 1225 – 1260 °C in the feeders [24].

In principle, the fiber forming process involves attenuating glass filaments continuously from a Pt – Rh bushing by applying a mechanic drawing force at offtake speeds of up to 80 m/s (Fig. 21). Bushings may have 400, 800, 1200, 1600, or more holes of 1 – 2.5 mm diameter. A single filament is drawn from each hole. The filaments are collected into a bundle (strand) and wound as a spun cake or directly processed into rovings, continuous strand mats, or chopped strands. The deformation during drawing is high: for example, with bushing-tip diameters of 2 mm and a filament diameter of 10 µm. A typical ratio of cross sections is 40 000 : 1 (Fig. 22).

Figure 21. Spin-draw process (schematic)
a) Bushing; b) Water spray; c) Sizing application; d) Strand guide; e) Spun cake

Formation of the filaments involves two basic processes:

1) efflux of molten glass from the bushing tips under the condition that

$$F_p + F_g > F_\eta + F_\sigma$$

2) drawing of the meniscus at the bushing tip to a continuous filament by a force under the condition that

$$F_d + F_g > F_a + F_\sigma$$

a) Bushing nipple; b) Drawing bulge D = hole diameter; d_f = diameter of glass filament

where
F_p = force due to hydrostatic pressure
F_g = force of gravity
F_σ = force due to surface tension
F_η = force due to viscosity
F_d = drawing force
F_a = sum of frictional forces

The viscosity of the melt must be increased sharply by cooling with air and water to enable a filament to be formed in the shortest possible time after the melt leaves the bushing tip.

An aqueous solution, called size or sizing, is applied to the cooled filaments; this solution consists basically of film formers, lubricants, and, if necessary, coupling agents. After the forming packages are dry, the sizing (0.5 – 1.5 wt %) has two functions:

1) Reducing the glass – glass coefficient of friction from ca. 1.0 to 0.2 to make further processing of the yarn possible. Due to the high coefficient of friction, textile glass strands without size cannot be processed further since they cannot be pulled off the cakes.
2) Imparting properties that are prerequisite for further application of the textile glass products as plastic reinforcement (plastic products) or as textile products with optimum weaving and desizing properties.

2.1.2.2. Glass Staple Fibers

The principles discussed with regard to the drawing of glass filaments also apply to glass staple fibers, but the manufacturing processes themselves are different.

In the *bushing blowing process,* the molten effluent is fibrillated by streams of gas. Adhesive sizing is added, and the fibers are collected on a rotating perforated drum or on a suction belt (nonwovens) under reduced pressure.

In the *drum drawing process,* fibers are drawn either from bushings or from rods by a rotating drum and scraped off. During the drawing process, sizing is applied to the fibers for later cementing. The fibers broken by scraping are swirled in a funnel.

In both processes the fibers are finally consolidated in a finishing tube and drawn off as a sliver. The sliver can be converted directly into fabrics, yarns, or plied yarns.

2.1.3. Textile Glass Products: Processing and Application

2.1.3.1. Product Designation

Glass filament and glass staple yarns have a standard form of designation.

Glass Filament Yarns (ISO 2078 and ISO 3598) EC9-34 Z28 – sizing x

E = E glass
C = continuous
9 = filament diameter in µm
34 = tex ∗
Z28 = Z-twist, 28 turns per meter

Glass Staple Yarns(ISO 2078 and ISO 3598) CD11-200 Z140

C = C glass
D = discontinuous
11 = nominal fiber diameter in µm
200 = tex ∗
Z140 = Z-twist, 140 turns per meter

∗ One tex is equivalent to 1 g/1000 m. For glass filament products the relationship between the number of holes in the bushing N, the filament diameter d_f, and the tex number is:

$$\text{tex} = 0.002 d_f^2 \times N$$

where d_f is in µm. The density of glass ϱ_G is taken to be 2.5 g/cm^3.

The other textile glass products are designated in a similar manner.

Typical properties of products used in textiles and plastics are summarized in Tables 7 and 8.

2.1.3.2. Correlation Between Processing and Application

Textile glass fibers can be processed as follows:

1) Textile processes such as weaving, knitting, and braiding, suitable for textile glass yarns, plied yarns, and rovings
2) Plastic processes for reinforcing thermosetting and thermoplastic resins, suitable for textile glass fabrics, layers, knits, mats, rovings, milled fibers, tissues, and chopped strands
3) Processes for reinforcing other matrix materials, e.g., bitumen, paper, rubber, gypsum, and plaster, suitable for textile glass fabrics, yarns, surface mats, rovings, and chopped strands

The processes used in plastic reinforcement are summarized in Table 9 (see next page).

Table 7. The tex number of textile glass yarns as a function of filament diameter and number of filaments in a strand

Filament diameter			Number of filaments per strand					
µm	Nominal µm	U.S. System	50	100	200	400	800	1600
5.2	5	D	2.8	5.5	11

2.1.3.3. Description of Textile Glass Products

There are separate standards for special products:

textile glass rovings	ISO 2797
textile glass mats	ISO 2559
textile glass fabrics	ISO 2113
glass filament yarns	ISO 2078 and ISO 3598
glass staple fiber yarns and rovings	ISO 2078 and ISO 3598

The entire line of products is presented in Figure 23 (see next page).

Textile glass yarns usually have a protective twist and are sold with textile or plastic sizes. Textile sizes based on starch/fats are especially suitable for high-speed looms, e.g., air looms. For certain applications, e.g., circuit boards for printed circuits, the textile finish applied to the fiber must be removed and replaced by an adhesive finish (coupling agent) via a special treatment given to the fabric.

Textile glass fabrics come in different weaves, depending on the application.

Textile glass rovings with untwisted, approximately parallel filaments or strands are offered with inside or outside take-off. Textile glass rovings are either assembled into a larger strand comprising several strands or produced by a direct process below the bushing. In the second process roving strands of various tex numbers are obtained by changing the number of holes in the bushing or by changing the filament diameters. Spun rovings of textile glass are suitable for the pultrusion process because of their good mechanical properties in the transverse direction.

Textile glass mats are made from chopped strands (chopped strand mats) or of strands laid up directly below the bushing (continuous strand mats). Consolidation in both cases is accomplished by chemical binders. Chopped strand mats are used primarily for hand lamination; continuous strand mats for all types of injection molding, compression molding, and continuous impregnation (Table 5).

Chopped strands with lengths of 3, 4.5, 6, or 12 mm have been found useful in the production of molding compounds and as reinforcement of thermoplastics. As shown in Figure 5, chopped strands are either cut directly below the bushing

Figure 23. Textile glass products
Stages 1 – 3 are in the hands of the textile glass producers, while Stage 4 is in the hands of the processors, e.g., weavers

or produced from intermediate products, e.g., textile glass roving or glass strands.

Milled textile glass fibers with fiber lengths of 0.2 mm are suitable as reinforcement of thermoplastics and polyurethane foams. In addition, they are used in the production of primers, fire-protection coatings, and the like.

Tissues of glass filaments or glass staple fibers are produced both by dry and wet processing. In both cases the fibers are chemically bonded.

Because of their bulky nature, *textured rovings or yarns* have turned out to be good replacement products for asbestos, e.g., in the manufacture of clutch facings. Textured yarns are also used in decorative fabrics.

*Layers*are planar structures of bonded, nonwoven textile glass yarns with crisscross or parallel yarns. Layers are primarily used for reinforcing paper or bitumen or in the preparation of prepregs (preimpregnated sheets).

*Textile glass knit goods*are more elastic than woven fabrics of textile glass. One area of application is medical bandages of pre-impregnated textile glass knits, which take the place of plaster casts.

Warp beams are used in the preparation of warps for weaving and consist of a multiplicity of yarns wound in parallel. Beams of strands with plastic sizing are used for unidirectional reinforcement of plastics for the bumper systems of motor vehicles.

2.1.3.4. Applications

As seen in Table 10 (on next page) there is a distinct trend toward the use of GRP in motor vehicles, both passenger cars and trucks. Glass fiber reinforced thermosetting resins are used in passenger cars primarily for body parts (hoods, tail gates) and for structural elements (bumpers, bumper supports). Glass fiber reinforced thermoplastics are used for operating parts within the engine compartment, noise suppressors below the engine, hub caps, etc.

Textile glass fabrics for *epoxy resin prepregs,* the basic material of circuit boards, is not considered to be GRP but rather is considered among

Table 10. Percentage of textile glass fibers used to reinforce resins by area of application in the Federal Republic of Germany, 1973 and 1985 [32]

Area	Thermosetting resins (except circuit boards)		Thermoplastic resins	
	1973	1985	1973	1985

Electronic industry	17	25	36	23
Other	6	3	2	3

other applications. However, it is the most important such other application, representing one-third of the amount used for other applications.

The following other applications are of importance:

1) Thermal insulation and heat protection (an asbestos replacement) with woven glass fabrics of glass filament and glass staple fiber yarns for primary insulation jackets, heat shielding curtains, fire blankets, pipe insulation, etc.
2) Wall coverings of staple fiber yarns
3) Plaster reinforcement of textile glass mesh fabrics and textile glass nonwovens
4) Reinforcement of grinding wheels with woven glass fabrics
5) Filter materials for high-temperature filtration with woven glass fabrics and nonwovens
6) Bitumen reinforcement with blend fabrics of glass staple fiber yarns, glass filament yarns, and textile glass nonwovens
7) Gaskets with glass cord and glass twine (an asbestos replacement)
8) Decorative fabrics of textured glass filament yarns and glass staple fiber yarns
9) Expansion joints of impregnated woven glass fabrics
10) Cable insulation and reinforcement with textile glass yarns
11) Reinforcement of adhesive tapes with textile glass yarns

2.1.4. Product Standards

The textile glass standards described in Section 4 contain supplementary basis sheets with specifications. Beyond that, there are customer acceptance standards, which list minimum requirements. In order for the values determined to be comparable and reproducible, standardized test procedures are used in which all testing conditions are specified precisely.

Processors of textile glass products should store the products in dry rooms at temperatures below ca. 25 °C at a relative humidity level between 55 and 65 %. Exposure to direct sunlight is to be avoided. Prior to processing, the material should be equilibrated under the temperature-humidity conditions present in processing.

2.1.5. Toxicology and Occupational Health

Textile glass products do not represent a health or environmental hazard, mainly because of the following properties:

1) Textile glass fibers do not contain poisonous and/or hazardous components.
2) Fiber structure, because of the chemical composition, is affected by body fluids in such a way as to reduce the carcinogenic potential.
3) Textile glass fibers do not split longitudinally, which largely prevents their penetration into the alveoli of the lungs.

Extensive systematic examinations of many thousands of people working for decades in the production and processing of textile glass products have shown that continuing exposure to textile glass fibers does not produce increased morbidity or mortality rates. Likewise, innumerable animal experiments (inhalation and ingestion of textile glass fibers as well as skin contact) have revealed no fibrinogenic or carcinogenic changes in test animals, a contrast to asbestos.

2.1.6. Economic Aspects

The growth of textile glass fiber production is illustrated by comparing the total figure of 1 135 000 for 1985 (Table 11) with that for 1973, 865 000 t. A 56 % increase was achieved.

Table 11. Production of textile glass fibers by final use and geographic region, 1985 [33]

Area	Production, t	
	Uses in glass fiber reinforced resins	Other uses, including fabrics for circuit boards
United States, Mexico, Canada	520 000	80 000
Western Europe	240 000	65 000
Japan and Korea	165 000	35 000
Eastern Europe, Former States of USSR, China	155 000	40 000
Others	50 000	
Total	*1 130 00*	*220 000*

2.1.7. Producers

The principal producers of textile glass fibers are listed in Table 12.

Table 12. Companies producing textile glass fibers and the location of their plants

Company	Location of plants
Asahi Fiberglass	Japan
Certain Teed Corp.	United States
Fiberglass Ltd.	Great Britain
Glaswerk Schuller *	Federal Republic of Germany
Manville Corp.	United States
Nippon Electric	Japan
Nippon Glassfiber	Japan
Nitto Boseki	Japan
Owens Corning Fiberglass	United States, Belgium, France
Pittsburgh Plate Glass (PPG)	United States
Scandinavian Glassfiber	Sweden
Silenka	The Netherlands
Skloplast	Former Czechoslovakia

Vetrotex	Federal Republic of Germany ** (Gevetex), France, Italy, Spain
Vitrofil	Italy

* Glaswerk Schuller specializes in staple fibers.
** The Vetrotex subsidiary Gevetex operates the plant in Germany.

2.2. Glass Fibers for Insulation

Glass fibers for insulation are fibers of vitreous structure produced from silicate melts by mechanical or pneumatic processes. For insulation, nontextile fibers are used exclusively. Such fibers are also called *glass wool,* slag wool, *rock wool,* or mineral wool.

While the manufacture of glass filaments goes back to antiquity, it was not until 1840 that the production of nontextile man-made mineral fibers (MMMF) was demonstrated in Wales [34]. This was an effort to utilize blast furnace slag and at the same time to find a replacement for natural asbestos. In the United States, rock wool production is documented to have taken place in 1893 [35]. An early patent for glass wadding by the centrifugal process was granted in 1912, but industrial exploitation of the process did not occur until 1930 [36]; the blowing process for glass wool, still in use today, was patented in 1933 [37].

The hope to replace asbestos could not be realized. Instead, these products found their own areas of application. Synthetic resin binders were developed around 1950, which made possible the production of dimensionally stable products and assured a uniform quality for insulation.

2.2.1. Physical Properties

Fibrous insulating materials of man-made mineral fibers are a highly disperse system of finely divided fibrous glass with a specific surface of $0.1-0.2\,m^2/g$. The fibers are oriented predominantly in the horizontal direction. For this reason, the material is isotropic in two dimensions but not in the third. It is an open-pore system with little resistance to flow. This is the basis for its thermal and acoustic properties.

The fiber diameters are distributed over a broad spectrum. The logarithm of the fiber diameter approximately follows a normal distribution (Fig. 24, see next page). The minimum fiber diameter is process dependent and is between 0.18 and 0.30 µm [38]. However, the properties of the individual fibers are less important than those of the final insulating material, i.e., the fibers and binder as a whole.

Table 13 (see page after next) lists the limiting temperature in use which is affected by the chemical composition, the fiber diameter, the amount and type of binder as well as the bulk density and the actual conditions of installation.

Figure 24. Distribution of fiber diameters in glass and rock wools

The most important property of insulation is the *thermal conductivity,* which is shown in Figure 25 for 14 mineral wools. The thermal conductivity of a particular fibrous material is determined by its bulk density ϱ_B and its average fiber diameter $\overline{D}$. The mechanical properties are primarily determined by bulk density and binder content; in any case, however, fibrous insulating materials cannot be used as load-bearing structural units.

2.2.2. Chemical Properties

Mineral wool insulation is inert to organic solvents, even at elevated temperatures. Extractables are mineral oils, emulsifiers, silicones, and low molecular mass components of binders.

Water and aqueous solutions attack the glass surface, the attack magnified by the large fiber surface. Attack by water also loosens the fiber–resin bond. Calciferous products (slag wool, rock wool) are soluble in acids and are attacked by acid flue gases.

2.2.3. Raw Materials and Chemical Composition

Glass wool (wadding, fibers) are produced from mixtures of minerals and industrial chemicals that produce the required final composition. In

Table 13. Chemical composition, fiberization process, and limiting temperature in use of glass fibers for insulation

	Glass wool			Rock wool				Slag wool

addition to quartz sand, the minerals used include limestone, dolomite, phonolite, feldspar, nepheline-syenite, kernite, colemanite, ulexite, and heavy spar (barite). The industrial chemicals include sodium carbonate, sodium sulfate, and barium carbonate. The use of recycling glass has gained considerable importance.

In contrast, rock wool and slag wool are, as a rule, prepared from a single mineral raw material of suitable composition, such as basalt, rhyolite, or diabase. To improve meltability, limestone is added as required. Table 1 shows examples of chemical compositions.

The mineral fiber is the predominant component of the insulating materials:

90 – 99.8 %	vitreous mineral fibers, average fiber diameter 3 – 6 µm
10 % max.	phenol – formaldehyde resins, frequently modified with urea or melamine
1 % max.	aliphatic mineral oil
0.2 % max.	emulsifiers, preferably nonionic polyethoxylenes
0.5 % max.	polymethylsiloxanol

2.2.4. Production

Melting. Two types of melting units are in use for the production of silicate melt: glass melting tank furnaces and cupola furnaces.

The *glass melting tank furnaces* are similar in construction to those used in other areas of glass manufacture [39]. Preferred are cross-fired recuperative furnaces and U-shaped flame furnaces, but all-electric melters are also used if energy costs are right. Maximum productivity is 300 t/d, and up to 3.5 $tm^{-2}\ d^{-1}$ can be achieved. *Cupola furnaces*are used to produce molten rock. They require coarse feed and yield a less uniform melt. The traditional fuel is coke but oil- or gas-fired units are also used. Furnace productivity rarely exceeds 150 t/d.

Fiber Production. Numerous processes and process variants have been developed for fiberizing silicate melt. Of these, only four have withstood the test of time (Fig. 26).

Owens Process. In the Owens blowing process (Fig. 26A), the melt, in the form of a thick primary strand, emerges from holes at the bottom of a platinum crucible (the bushing) and is subsequently entrained by a downward-directed stream of gas from the blow-jet. The blowing medium may be steam or compressed air. The primary strand is drawn to form fibers with an average diameter of 3 – 6 µm (Fig. 27). The length

Figure 25. Thermal conductivity of glass and rock wools as a function of temperature

of the fibers is about 3 – 10 cm. The product contains slugs. Glass and rock melts are processed in this way.

Rock Wool Process. This centrifugal cascading process (Fig. 26B) is also a one-step fiberizing process. A single stream of melt hits the face of a horizontal rotor which distributes it to two or three additional rotors; from which it is thrown in the form of fine fibers by centrifugal force. The fiber length is in the range 3 – 10 cm. The product contains slugs. Rock melts are used in this process.

Rotary Process. The rotary process (Fig. 26C) is a two-step process. The melt, in the form of a thick stream, passes through the hollow shaft of a rotating centrifuge into a rotating throw-basket of platinum or special steel, which distributes the melt evenly on the inside of a rotating spinner. Primary fibers issuing from holes in the face of this spinner, are entrained by the hot combustion gases of a circular burner and drawn to long fibers with diameters of 3 – 6 µm. The product is free of slugs (Fig. 28), but the process can be used only for "soft, long glasses," not for rock melts. The process is highly variable with respect to process parameters but is easy to control.

Other Processes. The centrifugal blowing process, shown in Figure 26D, is of little significance in the production of slag wool. The rod drawing process and a variant of the blowing process serve to produce textile glass fibers for glass mats. Special glass microfibers are made by the flameattenuation process. However, these

Figure 26. Fiberization processes

Figure 27. Scanning electron microscopy (SEM) photograph of rock wool produced by the Owens process

Figure 28. SEM photograph of glass wool produced by the rotary (TEL) process

processes have limited productivity and consume large amounts of energy for fiberization,

and therefore they are not used to produce fibrous insulating materials.

Product Forming. The fibers are formed into a continuous sheet by pneumatic processes, while an aqueous solution of binder is sprayed onto the freely falling individual fibers. The binders are slightly pre-condensed phenol–formaldehyde resins. They are often modified by aminoplastic resins (urea, melamine, melamine ether, dicyanodiamide) to suppress the tendency of phenolics to exothermally autoxidize. In the industry these aminoplastic resins are called antipunking agents.

Figure 29 shows schematically the overall manufacturing process. The binder resins are cured at temperatures around 180–250 °C in a continuous flow dryer heated by circulated air. For shaped articles or pipe insulation, for example, special ovens that operate on a similar principle are used. On the other hand, presses with purely convective heat transfer are rarely used since they require long cycle times.

Mineral-fiber insulating materials can be cut to any desired dimension with knives, saws, shears, and milling cutters.

2.2.5. Environmental Protection

Characteristic emissions arise in the various stages of producing insulating material from mineral fibers. Emissions from the melting units are similar to those of other glass melting installations. Electric precipitators have proved useful in dust removal but greatly strain the fluegas conditioning system. They can be combined with the usual wet and semi-wet installations for sorption of fluorine and desulfurization.

The binder resins should contain a minimum of monomers. Lubricants, mineral oils, hydrophobic agents, and other organic additives must be selected with an eye to their volatility. Scrubbing systems with wet electric precipitators or deep-bed aerosol separators are suitable for minimizing emissions.

Wastewater from the manufacturing plant is biodegradable. Treatment with municipal wastewater is always preferable. The high water requirements of the off-gas conditioning system favors installation of closed circulating systems with the result that manufacturing plants can be operated free of wastewater.

Local ordinances must be observed in removing process waste. The insulating material itself, like other building materials, is inert and does not have the potential for endangering water. Both the dust from the filter units and the process waste is suitable for internal recycling. The fiberization units are serious noise emitters; therefore, the manufacturing plant must be housed in massive buildings.

The overall effect of mineral-fiber fibrous insulating material on the environment is positive.

Figure 29. Mineral-fiber insulation, from raw material to product [42]
The rotary process is used to form fibers.

There is no other building material that offers a similar potential for minimizing the consumption of primary energy for the same raw material and energy requirements. Average energy amortization times of 0.3 years and ecological amortization times of less than 0.1 years have been calculated.

2.2.6. Quality and Analysis

Each country has very detailed standards for fibrous insulating materials. International standardization is in progress, e.g., in the areas of thermal insulation in high-rise construction, fire protection, and industrial acoustics [43].

Figure 30 shows a scheme of analysis for mineral-fiber insulating material. Glass analysis alone is, as a rule, not sufficient to identify the producer. However, analysis of characteristic trace elements generally allows identification of the producer. Certain finishing specialities of the final product may permit identification.

From the ecological point of view, an eluate analysis is essential. The eluate is obtained by shaking the insulating material at room temperature with a tenfold amount of water for 24 hours.

For the determination of formaldehyde, the perforator method DIN-EN 120 and the gas analysis method of DIN 52693 are suitable. Analogous methods are specified in other countries.

2.2.7. Applications

Mineral-fiber insulating materials are finished products for use in protection from heat, cold,

Figure 30. Scheme of analysis for mineral-fiber insulating materials

fire, and noise. The major end use area is high-rise construction. Considerable quantities are used in industrial and machine construction for thermal insulation. Fibrous insulating materials are also important as noise absorbers in buildings and elsewhere.

Economic Significance. World production of mineral-fiber insulating material reached a maximum of ca. 6×10^6 t in 1980 and has stagnated since (Table 14). About 75 % of the total is produced in the industrialized countries with temperate and subarctic climate. Consumption is closely tied to investment and building activity. About 60 % of the demand for insulation in industrialized countries is met by mineral-fiber insulating material.

Table 14. Production of mineral-fiber insulating materials in various geographic areas, 1973 and 1983.

Area	Production				
	1973		1983		Increase, %

Other			250 000	5	
World total	3 750 000	100	5 600 000	100	49.3

2.2.8. Toxicology and Occupational Health

Synthetic mineral fibers are hard, abrasive materials. Constant handling can damage the epidermis, especially the finger tips and other exposed areas of the body. Therefore, work gloves should be worn, and the skin should be kept smooth by applying oily, protective skin lotions.

The fibrous dust formed during mechanical loading, cutting, sawing, or rubbing may irritate the skin or the mucous membranes. Especially the coarse fibers, with diameters greater than about 12 µm, and the nonfibrous components are able to penetrate the epidermis, thus causing injuries and facilitating the entry of germs. The irritations are slight and rapidly heal with normal body hygiene.

Ordinances pertaining to protection of the workplace prescribe a general permissible limit of dust; in most countries, this limit is 5–10 mg/m^3. In the Federal Republic of Germany the limit is 6 mg/m^3. Epidemiological investigations suggest that there is no health risk associated with the handling of mineral-fiber insulating material if these limits are observed.

Suspicions of a *carcinogenic potential* were derived from animal experiments with extremely fine glass fibers carried out in 1972–1978. Up to now these suspicions have not been confirmed with fibers from insulating materials. Animal experiments involving dust inhalation gave no indication of carcinogenicity. Extensive epidemiological investigations could neither confirm nor deny these suspicions. Further research is needed.

Fibrous insulation materials are free of preservatives, fungicides, or biocides. They do not contain asbestos or silicogenic material. Formaldehyde is usually absent or present only in trace amounts (<10 mg/kg).

3. Refractory Fibers

Refractory fibers are used at temperatures in excess of 1000 °C. They are distinguishable from mineral and synthetic aluminosilicate fibers by their greater durability at high temperature and by the fact that they have polycrystalline microstructures rather than being amorphous. They are relatively new products, having only been developed during the last 20 years, and additional varieties continue to be announced at a significant rate. The majority of fibers of this type have been developed for thermal insulation at high temperatures or for advanced composites having the special physical properties required in aerospace applications. These materials are expensive since they are still manufactured on a small scale.

Historical Background. Until the 1960s, refractory fibers were either naturally occurring fibrous minerals of the asbestos type or melt-spun glass fibers such as E glass, rockwool, or kaolin-derived fibers. Their maximum use temperatures were limited by their melting points, kaolin fibers having the highest use temperature of 1250 °C. Since then more refractory grades

of melt-spun kaolin fibers, capable of use up to 1400 °C, have appeared.

The development of several types of novel oxide fibers since 1970 has had several motivations. At the time, an awareness was developing that a safe, noncarcinogenic, cheap asbestos replacement might be possible. Asbestos was widely used in medium-temperature insulation, in textiles, and in friction materials so that replacement in these uses appeared to be an attractive technical target. About the same time the worldwide rise in oil prices increased the demand for energy-saving insulation, especially in high-temperature furnaces operating above 1250 °C. Consequently the need for improved fiber refractoriness and freedom from nonfibrous impurities (combined with an awareness that very fine fibers like asbestos might be carcinogenic) lead to the development of new high-alumina and zirconia staple fibers. Simultaneously, continuous textile-grade multifilament fibers have also been developed to satisfy the need for high-temperature resistant textile applications such as furnace curtains, fire barriers, hot gas filters, electrical insulation, and protective fire-fighting suits. In the 1980s renewed interest in the potential of metal-matrix composites is also sustaining the further development of novel high-alumina fibers.

During the 1960s the needs of the U.S. aerospace program for high-modulus, low-density reinforcing fibers led to the development of entirely new non-oxide fibers; initially to CVD boron fiber and later to carbon fibers. To a large extent the development of cheap, high-quality, carbon fibers in the 1970s has overtaken that of boron fiber since the price of the latter has not been reduced significantly. A major disadvantage of carbon and boron fibers is their ready oxidation at moderate temperatures, and so during the late 1960s and 1970s various kinds of oxidation-resistant silicon carbide fibers have been evolved. For example, the makers of CVD boron have turned to CVD silicon carbide as a potentially cheaper and better product. Another driving force in the development of continuous textile-grade silicon carbide fibers (such as Nicalon) has been the desire to have good high-temperature properties combined with resistance to oxidation and to attack by molten metals. At present, therefore, advanced oxide fibers and silicon carbide variants represent the two main categories of refractory fibers.

The chief materials of interest are boron [*7440-42-8*], silicon carbide [*409-21-2*], high-alumina [*1344-28-1*] (0 – 30 % SiO_2/Al_2O_3), and zirconia-based [*1314-23-4*] products. For each of these materials there is a choice of several grades from a range of suppliers. Fibers are available in a variety of primary forms such as continuous multifiber yarn, short staple random fibers, or as whiskers (→Whiskers). Typically, products have diameters within the range 1 – 150 µm. Some of these primary products may be converted easily to secondary forms such as woven cloths, ropes, papers, boards, prepregs, etc. All products on the market have complex compositions and microstructure so that each can only be referred to uniquely by its trade name. These are listed in Table 15.

Other materials that are or have been available in fiber form are boron carbide (B_4C), silicon nitride [*12033-89-5*] (Si_3N_4, whiskers), and boron nitride (BN). For these materials the supply situation varies since their applications tend to be highly speculative.

3.1. Properties and Raw Materials

3.1.1. Physical Properties

The behavior of fibrous materials is strongly dependent on the shape and diameter of the fibers. Typically the finer fibers are in diameter, the more flexible they become and the more difficult it is to pack them into high volume fractions. Fine random staple and whisker fibers are usually low bulk density materials, while thick monofilament or multifilament continuous fibers, which are both more rigid and less flexible, are easily packed into high volume fractions (60 % for example).

These characteristics determine utility and the methods of handling. Fine staple fibers are easily used as low density thermal insulation and for the manufacture of low volume fraction composites, but may present dust problems in handling. Large diameter continuous fibers are more readily woven into textile forms for high-temperature use and are also more readily made into unidirectional high-volume fraction composites. On the other hand, the main handling

∗ In air, fiber strength severely affected.

risk is skin irritation caused by penetration of the rigid fibers.

The physical properties of most importance are fiber diameter, length, shape, density, modulus, tensile and compressive strength, expansion coefficient, thermal conductivity, and maximum working temperature. These are summarized from available manufacturers brochures in Table 15.

Only data on fibers with diameters greater than 1 μm are reliable. Data for finer whiskers are implicit from data on composites. Nevertheless, single crystal whiskers of silicon carbide have the best mechanical properties (modulus around 600 GPa, strengths up to 20 000 MPa). Polycrystalline Avco silicon carbide and boron and Du Pont α-alumina are of comparable stiffness, but Du Pont alumina is weaker than the others (modulus about 400 GPa and strengths 1500 – 5000 MPa). Finally polycrystalline transition aluminas, mullites, and Nicalon have moduli around 200 GPa and strengths around 2000 MPa. In composite applications specific modulus and strength are more important, and here boron possesses the greatest advantage since its density is the lowest. Silicon carbide and transition aluminas follow at ca. 3000 kg/m^3, while α-alumina and zirconia-based fibers follow with densities of ca. 4000 kg/m^3. Figure 31 shows SEM microphotographs of three different refractory fibers.

3.1.2. Chemical Properties

Refractory fibers as a class of materials are of low reactivity. The chief area of concern is their resistance to oxidation at high temperatures and, if used in metal – matrix composites, their inertness to corrosion by metals during fabrication and use. Reported thermal data are also given in Table 1, including claimed maximum use temperatures. Boron fibers are the most reactive towards oxidative and metallic attack. Several attempts have been made to coat boron fibers with inert layers, which has led to the BorSic product (SiC-coated boron). The chemical vapor deposition process for making boron fibers lends itself to laying down additional coatings. In France boron carbide-coated boron has also been tested [44].

The properties of silicon carbide fibers and whiskers in composites have been thoroughly reviewed by Andersson and Warren [45,46]. Their resistance to metal attack exceeds that of boron by 200 – 300 °C. High alumina fibers are inert in air and light alloys, but are slowly attacked by hot strong acids or alkalis. Zirconia fibers have exceptional thermal stability and are also resistant to hot alkali.

3.1.3. Resources, Raw Materials

The raw materials for refractory fibers are usually specially selected intermediates. Since the elements needed are among the most abundant,

Figure 31. SEM microphotographs of several refractory fibers; scale: —⟶—10 μm
A) Silicon carbide whiskers; B) Aluminum oxide staple fiber (Saffil, ICI); C) Titanium-modified silicon carbide fiber (Tyranno, Ube Industries)

there is no shortage of primary sources. The intermediates, however, are only readily available in industrialized countries. In the case of silicon carbide whiskers, a process has been commercialized which uses rice hulls as raw material [47].

3.2. Production

Because of their relative novelty, the processes for making refractory fibers are almost all proprietory, and full details have never been published. A summary of the patent literature [48] since 1970, relating to both the production of refractory fibers and their uses in composites, has appeared. There is a special section on refractory fibers in BELA VON FALKAI's book [49]. For further useful information refer to [50, 51].

3.2.1. Boron Monofilament

CARLSSON [52] has reviewed general methods of making boron fibers. In the 1960s, Avco (USA) developed a chemical vapor deposition (CVD) process to make 140-µm boron monofilaments having an 8-µm tungsten core [52, 53] on a scale of 15 t/a. According to the company's latest brochure, the present capacity is only slightly greater. More recently, a cheaper variant was made available, in which the core is a 30-µm carbon fiber, but this has now been withdrawn. This development was initially financed by the U.S. Government to develop advanced composites for use in the space shuttle and in aerospace applications [53].

The process deposits amorphous boron with a nodular morphology from a BCl_3–H_2 mixture onto the electrically heated tungsten core at ca. 1300 °C.

$$BCl_3 + 3/2\,H_2 \rightarrow B + 3\,HCl$$

The operation is carried out in single-stage or two-stage tube reactors (Fig. 32), the filament passing at 3 – 4 m/min through mercury seals, which also act as electrical contacts. Control of deposition temperature is critical because too high values lead to crystallization of the boron, which reduces the strength of the filaments. Auxiliary heating techniquescan increase quality

Figure 32. Apparatus with mercury seals for the preparation of boron fibers by two-stage chemical vapor deposition [76].
a) Apertures (25 – 254 µm diameter); b) hydrogen feed tube; c) BCl_3 feed tube; d) Mercury pool; e) Tungsten wire substrate; f) Gas effluent; g) Power supply (d.c.)

and output. A range of products with various diameters has been produced. Initially, the tungsten core made up a large proportion of raw materials costs, but later the price of tungsten dropped, and larger diameter fibers were developed so that this cost factor decreased in importance. The introduction of carbon-cored B filament has lead to further cost reduction [53]. Various surface treatments, such as acid polishing, have been investigated to increase the strength from 2 GPa to 5 – 7 GPa. Also surface coatings such as silicon or boron carbide are applied by

the CVD technique [54] to reduce the reactivity with aluminum alloys and oxidation at temperatures above 300 °C.

In the commercial plant, hundreds of reactors are fed in parallel with the gaseous reactants. Since the conversion of gas per pass is low, the unconverted gases are recovered and recycled, while the byproduct HCl is sold.

More recently, more rapid boron deposition methods have been reported: these methods operate at high temperature and high pressure and do not require resistive heating of the substrate. Pulse discharges have been used for boron coating of filaments [55]. The excited gas species are formed by inductive or capacitive coupling of pulsed high electric power to a boron-containing gas mixture at a pressure of 0.1 – 0.3 MPa (Fig. 33). The gases admitted to the deposition zone are hydrogen, mixed with boron halides, boranes, or alkyl borates. The deposition process is performed at 20 – 350 °C on filaments suspended in the deposition zone: tungsten filaments, graphite yarn, and polyacrylonitrile yarns were coated with boron to a thickness of about 50 µm. The residence time of the substrate within the deposition zone was about 5 min.

3.2.2. Silicon Carbide Fibers

Because of the highly attractive physical properties of fully crystalline silicon carbide and the low cost of raw materials, more effort has been devoted to generating silicon carbide in fibrous forms than for any other material [45, 46, 56].

Silicon Carbide Monofilament. This material is available in composites from Avco and is probably made by a CVD process [57] similar to that used for boron filament. The reagents are an alkylchlorosilane or a mixture of alkane and chlorosilane condensed onto a tungsten or carbon core. The product has a columnar grain structure with the growth direction normal to the fiber axis. In order to increase the strength of the fiber it is usually coated with a thin carbon layer (CVD process), which fills in any grain boundary faults at the filament surface.

Silicon Carbide Continuous Yarn. Silicon carbide continuous yarn was invented by S. Yajima in the 1970 – 1975 period and has since been commercialized by Nippon Carbon Co. as Nicalon [58]. A second generation carbide fiber, namely Tyranno fiber from Ube Industries, contains titanium in addition to silicon and is reported to have superior strength and chemical resistance.

The Nicalon fiber process begins with the conversion of dimethyldichlorosilane (an intermediate in silicone manufacture) to poly(dimethylsilane) by dechlorination with sodium. The poly(dimethylsilane) is heated under Ar in an autoclave at 470 °C for 8 – 14 h to convert it to a poly(carbosilane) of complex structure (see [58]). After vacuum distillation to 280 °C to remove low molecular mass fractions, the poly (carbosilane) (M_r 1500) is then melt-spun at 350 °C as a multifilament tow. The raw fibers are then cross-linked by oxidation in air for 30 min up to 190 °C and heat-treated to 1200 °C in inert atmosphere to convert them to the fin-

ished fiber having maximum strength. The fibers have a complex constitution consisting of a fine-grained mixture of graphite, β-SiC, and glassy silica. The fiber stability is limited above 1200 °C, and the modulus (which is a function of fiber diameter) is only 50 % of the value of CVD polycrystalline silicon carbide.

Silicon Carbide Whiskers (→Whiskers, Chap. 4.1.). These have traditionally been made by high-temperature synthesis between SiO_2 and a carbon source under reducing conditions. A more recent development uses as raw material rice hulls, which contain Si and are processed at 1500 – 1660 °C [47, 59]. They are usually single crystals, although there is some confusion in the literature as to the direction of the growth axis. Very high strength β-silicon carbide whiskers (6 µm diameter) are grown by a vapor – liquid – solid (VLS) method at 1400 °C from methane and silicon monoxide using powdered iron catalyst [60, 61]. Properties are given in Table 1.

3.2.3. High Alumina Fibers

High alumina fibers containing less than 30 wt % SiO_2 cannot be readily spun from melts because the temperatures are too high. Fibers in this class are either made from water-soluble or dispersible precursors (sol – gel products) or from an organometallic precursor (only Sumitomo's alumina). Fibers that are available range from fine diameter (3 µm) random staple (ICI Saffil alumina fiber) through to relatively coarse (20 µm) continuous fibers (Du Pont FP alumina). This class includes mullite [*1302-93-8*] fibers (27 % SiO_2) and 3 M Nextel alumina – boria – silica fibers. Single-crystal whisker products are also available (→Whiskers, Chap. 4.3.).

Continuous Yarn Fibers. Du Pont, 3 M, and Sumitomo have supplied products of this type for several years. ICI, Denka Kagaku, and Mitsui mining announced new alumina-based continuous or semicontinuous fibers.

In each case a different precursor is used, but the processes are otherwise broadly similar (Fig. 34, see next page). First a viscous precursor solution is prepared and then converted to green (or gel) fibers by extrusion through multi-hole spinnerets. The gel fibers are converted to refractory fibers by heat treatment, usually in multistage furnace treatments. Major features of these processes are the ability to make any composition and the large shrinkage experienced during calcination.

According to patents [62, 63], Du Pont's FP fibers may be made from colloidal α-alumina (e.g., Alcoa XA16 fractionated to 90 % <0.5 µm diameter) dispersed by HCl treatment and blended with an aluminum salt, such as the chlorohydrate (commercially available basic aluminum chloride [*1327-41-9*], $Al_2(OH)_5Cl \cdot 2-3\,H_2O$), acetate, or nitrate. The viscous mixture is extruded into air to give gel fibers, which are then subjected to two- or three-stage calcination to give the final fiber (either flame-polished in an oxypropane flame or at 1400 – 1500 °C in a furnace). The fibers have a diameter of 20 µm and are polycrystalline α-alumina with a grain size <0.5 µm. Their strength can be improved by a surface coating ca. 5 nm thick of silica derived from a silicone [64].

According to a patent [65] 3 M's Nextel fibers are made from a silica hydrosol blended with aluminum formoacetate and boric acid together with organic improvers such as polyvinylpyrollidone (PVP), poly(vinyl alcohol) (PVA), lactic acid, or glucose. After concentration to a viscosity between 45 and 500 Pa · s, the solution is extruded through a multi-hole spinneret into air to give gel fibers. These gel fibers are calcined in air to at least 1000 °C (polycrystalline η- or γ-alumina <60 nm grain size) or to 1400 °C (polycrystalline mullite >50 nm grain size) if they are to be used up to 1400 °C. The finished fibers have an oval cross section with a mean diameter of 11 µm and are suitable for weaving cloths.

Sumitomo has described their process [66, 67]: first triethylaluminum or triethoxyaluminum is hydrolyzed with a controlled amount of water to a polyalkyl(oxy)aluminoxane (degree of polymerization of 10 – 200), which is then dissolved in an organic solvent. An alkyl silicate is added (to give 15 wt % SiO_2 in the final product) to prepare the viscous solution (0.1 – 500 Pa · s) for spinning. The fibers are dry-spun into air. These gel fibers are then calcined in air to 700 °C to decompose them to oxide and further fired at 1000 °C to crystallize them to a dense

polycrystalline fiber having a γ-alumina and/or a mullite structure with a grain size of several nanometers). Production fibers are made with a diameter of 17 µm.

So far no details are available for methods of producing the newest continuous fibers.

Staple Fibers. Staple fiber products include ICI Saffil alumina, Carborundum's Fibermax (and the equivalent Toshiba Monofrax), and several products available from Japan such as Denka's Alcen.

In sol–gel processes [68], an aqueous spinning solution is formulated from basic aluminum chloride (aluminum chlorohydrate, $Al_2(OH)_5Cl \cdot x\,H_2O$), a water-dispersible siloxane, or a silica sol, and a viscosity modifier such as PVP, PVA, or poly(ethylene oxide). Fibers are either blow-spun through multi-hole spinnerets or centrifugally spun into warm dry air and collected as a random mat on a conveyor belt. They are decomposed at 200–500 °C and calcined in one or two stages to recrystallize and sinter the initially amorphous material. Various products are available, with different finishing temperatures and containing different crystalline-transition alumina phases (Table 1). Centrifugally spun products contain more nonfibrous material than blow-spun products.

3.2.4. Zirconia Fibers

Zircar fibers (yttria stabilized) are made by the relic process, where a continuous cellulose fiber is impregnated with suitable salts and then calcined in air to decompose the salts to oxides and burn away the cellulose. Yttria is added to maintain the zirconia in the tetragonal phase, preventing the destructive conversion to monoclinic phase on cooling. Alternative phase stabilizers

that have been investigated are calcium oxide and magnesia. An alternative process, which has been used by ICI to make staple fibers, is the sol – gel route. This is described by others in the literature [69] and generally uses zirconyl acetate as the raw material. Other details are similar to those used for alumina fibers. Nextel Z-11 continuous zirconia – silica [*14940-68-2*] fibers from 3 M are made much like the alumina – silica – boria products [70].

3.3. Environmental Protection

Since these products have only been made in small quantities so far and are physically and chemically inert under ambient conditions, they pose no significant threat to the environment. Ultimate disposal is likely to be by burial. The byproducts of fiber manufacture are either acids, which are scrubbed and sold or neutralized before disposal, or carbon oxides and small amounts of volatile organic compounds.

3.4. Uses

The principal uses of refractory fibers are in high-temperature insulation and composites.

3.4.1. High-Temperature Insulation and Filtration

By reason of their refractoriness, those fibers which are not attacked by oxygen or which form passive oxide layers (oxides, SiC) can be used in furnaces as high-temperature insulation or structural elements. High-alumina fibers dominate these applications. In general, the staple and whisker materials that have diameters below 6 μm are best for low-density insulation having a low thermal conductivity. Conductivities at 1400 °C as low as $0.3 - 0.4\,Wm^{-1}\,K^{-1}$ can be reached. Use of such low thermal mass insulation allows faster cycle times in batch furnaces, giving energy savings of 20 – 40 %.

In furnace applications, the short fiber products can be used in a variety of forms. When resilience is required, blanket or loose wool can be employed in several ways. In one method, strips of blanket are glued to a rigid backing (stack-bonding) to give a surface with high gas erosion resistance. This technique can be applied to existing brick-lined gas-fired furnaces (veneering) to give substantial energy savings. Staple fibers can also be converted by wet-lay vacuum-forming processes to rigid forms. For such products the refractory fibers are often blended with amorphous alumino-silicate fibers so as to uprate the maximum working temperature of the amorphous fibers, e.g., from 1250 to 1400 or 1500 °C. In these forms, sacrificial organic binders, such as starch, are often combined with a refractory binder such as a silica sol. It is also possible to make papers by blending small proportions of fine glass fibers into the slurry.

Thermal insulation for nuclear reactors presents a requirement of high resilience under high acoustic vibration loadings at modest temperatures. Very low shot level staple fibers are superior for this application.

The yarn and monofilament materials are best used as woven cloths [71], which can be employed as flame barriers and radiation shields or as bag filters for hot-gas filtration. Where density is not a prime consideration, Nextel Z11 is claimed to have superior firewall properties. The long fiber products can be converted to string, woven cloths, ropes, tapes, thread, braiding for electrical wiring, etc. Such yarns, ropes, etc. can be employed as expansion joint packings, door seals, and the like. Both staple and continuous fibers can be used for space vehicle insulation systems, e.g., tiles as on the space shuttle.

Both short and long fiber products can be used in advanced composites. Large volumes of data are available for composite properties using either resin matrices, metal matrices, or ceramic matrices. These present a range of opportunities.

The refractory properties of the fibers are most effectively exploited in metal – matrix or ceramic – matrix composites because good properties are then available above 200 °C in many such systems. Both types of material are presently undergoing intensive development to evaluate their potential for replacement of conventional metal alloys.

Resin-Matrix Composites. In resins, refractory fibers are in competition with carbon fibers and Kevlar fibers. In situations where the composite is required to have high compressive

strength, the use of boron, silicon carbide, or alumina fibers is preferable. This has found utility in parts of sporting goods such as golf clubs, tennis rackets, and fishing rods. Aerospace applications have also been explored [53]. The U.S. F14 fighter had boron – epoxy horizontal-stabilizer skins. Where electrical insulating properties as well as mechanical properties are important, then alumina or silicon carbide fibers can be more effective than glass or Kevlar fibers.

Metal – Matrix Composites. Metal – matrix composites (MMCs) where the matrix is an aluminum, magnesium, titanium, or nickel alloy, should be able to replace parts currently made of steel, titanium, or nickel alloys. Fabrication and shaping of MMCs presents formidable problems. Corrosion of fibers by the metal during fabrication and use is the chief problem. Aluminas are superior in this respect to silicon carbide and boron, which, for example, is only stable to 200 °C in 2024 aluminum alloy. However, boron fibers are usable when SiC-coated. Because of high costs, nearnet-shape forming methods such as squeeze-casting, extrusion, and forging are preferred. Aluminum-based MMCs have reached commercialization in a few applications. Boron filament – aluminum composites have been utilized for cargo bay spars in the space shuttle. In the future, other fibers, such as silicon carbide (continuous and whiskers) [72, 73] and alumina [74], will find uses in aerospace and automotive engineering applications where low density must be combined with rigidity, strength, heat, and/or wear resistance.

The use of small amounts (<30 vol %) of short alumina fibers in diesel engine pistons has been commercialized by Toyota. Here the effect of fibers is to increase the wear resistance of the piston alloy in the region of the ring grooves so that high nickel alloy inserts are not required. In more advanced applications such fibers in piston crowns can increase resistance to fatigue cracking so that more efficient engines become possible. High volume fractions of unidirectional long alumina fibers are currently being evaluated in connecting rods for internal combustion engines to decrease the mass of moving parts, which should lead to increased engine efficiency.

BorSic and silicon carbide monofilaments have been successfully incorporated into Ti-6Al-4V alloy [44] with the aim of increasing the maximum operating temperature of this alloy, but this matrix is generally too aggressive to be compatible with other types of fibers.

Ceramic – Matrix Composites. When materials are required to exceed the maximum working temperature of nickel-based superalloys, ceramic – matrix composites are forecast to fill the gap. If the more severe processing and property requirements can be met, they will be utilized in advanced gas-turbine blades and in advanced internal combustion engine components such as pistons and exhaust turbo-charger rotors.

Currently much effort is devoted to improving the fracture toughness of monolithic engineering ceramics such as glasses, glass ceramics, silicon carbide, silicon nitride, alumina, and partially-stabilized zirconia by the incorporation of fiber reinforcement. This is the most severe application of refractory fibers since they are required to resist corrosion by the matrix during fabrication of the composite at temperatures often exceeding 1200 °C. Some encouraging results have been reported in the literature [57], but a real application has not yet been successful.

3.5. Miscellaneous Uses

Miscellaneous applications of refractory fibers have developed, such as the use in nuclear technology. Here, boron fibers find uses in fabricating flexible neutron shields.

Zirconia fibers find utility because of their great resistance to alkali attack and are recommended for use as battery separators. Nextel Z-11 has outstanding flame resistance and is preferred for fire-wall uses.

Porous fibers, such as ICI catalytic grade Saffil alumina, have been found to be effective as catalyst supports in domestic flameless heaters.

3.6. Economic Aspects

Refractory fibers are specialities made on a relatively small scale where raw materials costs make little contribution to the selling price. The major costs are related to processing and capital costs.

Of all the fibers considered, short staple alumina fibers are the product available in the greatest quantity and at lowest price. World capacity probably exceeds several hundred tonnes per year. Prices range from \$ 30 to \$ 60 per kg (ca. 30 – 60 €/kg).

Prices for continuous fibers or whiskers vary from \$ 80 – 900 per kg. The cheapest is Nextel 312 at \$ 80 per kg with Nextel 440 at \$ 260 per kg. SiC whiskers, Nicalon, Sumitomo alumina, and DuPont FP fibers all cost ca. \$ 450 – 550 per kg, while Avco boron fiber (tungsten core) is \$ 825 – 900 per kg. These products are all probably made on a 10 – 20-t/a scale. Du Pont has projected that at 500 t/a FP alumina fiber would cost \$ 88 per kg.

Secondary forms of the above materials–such as vacuum-formed shapes for staple fiber or woven cloths for continuous fibers–can cost double the basic fiber cost. Some products are available as epoxy prepregs, and there is an appropriate markup in price for such intermediates.

3.7. Toxicology and Occupational Health

Fibers with diameters exceeding 3 µm are not respirable and, like glass fibers, are difficult to handle only because of skin irritation. For such materials, operators handling the fibers are recommended to wear loose-fitting clothing.

Fine fibers with diameters below 3 µm are respirable. Because of the known ability of asbestos dust to cause both asbestosis and mesothelioma, considerable effort has been devoted to assessing other fibrous mineral and ceramic dusts for similar effects. In general, suspicion has now focussed on those materials that are durable in the body and have diameters below 0.5 µm and lengths greater than 8 µm [75]. Products that have diameters significantly above this limit have been found to be inert biologically. According to a proposal, such materials should be classified as nuisance dusts, for which an MAK of 6 mg/m^3 is appropriate. In the UK and the United States the MAK is 10 mg/m^3. The finer materials, especially whiskers, remain under suspicion. Similar products have been withdrawn from the market because animal tests have proved them to have positive carcinogenic potential. For such materials an MAK equivalent to that of asbestos has been recommended until more definitive information is available.

4. Metal Fibers

The definition for a metal fiber is not straightforward, especially when metal fibers are classified according to nature, structure, properties, or manufacturing processes. What cannot be considered a metal fiber is easier to state:

A single drawn wire used separately; anything much thicker than 100 µm; and steel wool. Metal fibers can usually be handled in the same way as textiles, paper, or polymers, and have small, equivalent diameters.

In this chapter, emphasis is placed upon bundle-drawn and melt-spun fibers. For metal whiskers see →Whiskers. Other methods of manufacturing fibers are mentioned briefly.

4.1. Production

4.1.1. Bundle Drawing

Very fine wires can be produced by wire drawing. Production costs are extremely high, however, and increase exponentially as the diameter decreases. To overcome this problem bundle drawing was developed as early as 1936 [78]. Instead of drawing wires singly, a number (in some cases several thousand) are bundled and drawn simultaneously [79] (Fig. 35, see next page). The sole difficulty remaining is to separate the individual fibers with a suitable material prior to bundling so that the final fibers can be individualized again. Quite often used is another metal that has sufficiently similar properties to the wire metal to be made into fibers, to withstand the drawing and annealing operations, but a lower chemical resistance to allow the fibers to be freed from this matrix in a leaching operation. Whereas this method greatly reduces drawing and annealing costs, it only produces bundles of fibers and not reels of single wires such as is needed to produce fine tungsten wire to serve as core material for boron fiber manufacturing.

4.1.2. Melt Spinning [80–82]

The basic idea behind all the from-the-melt production methods is the possible economic advantage of single-step processes over conventional time- and energy-consuming, labor-intensive fiber-drawing processes. These from-themelt processes can be roughly divided into two classes: melt extrusion and melt extraction. Dating back to the 1930s, from-the-melt fibers developed rapidly in the 1960s after Duwez developed the splat cooling technique: a revolution in metallurgy, resulting in what are now generally known as the RST (Rapid Solidification Techniques), sparked intense interest in glassy or amorphous metals. The Battelle Development Corporation has pioneered all these processes in one way or another, and is still doing so.

Figure 35. Manufacturing alternatives of bundle-drawn metal fibers

Melt Extrusion. Melt extrusion (melt spinning) involves the solidification of a liquid jet of metal extruded through an orifice (Fig. 36). The stream of molten metal is inherently unstable, mainly due either to its high surface tension and low viscosity or to a violent drop in its viscosity at its spinning temperature.

Figure 36. Melt spinning of metal fibers.
a) Crucible; b) Nozzle

The stream must be stabilized. There are a number of variants, which can be grouped in four divisions:

1) Jet stabilization in a controlled atmosphere, triggering off a surface reaction and oxide film formation (e.g., Monsanto, Michelin, Bekaert, Brunswick).
2) Jet stabilization by sheathing in glass and spinning the resulting composite. This so-called Taylor process (Fig. 37) has been successful on a semi-industrial scale (Glass Development, U.K.), but has virtually been abandoned in spite of the excellent fiber quality, mainly because of low production capac-

ity, hence high cost. Fibers down to 1 μm are possible.

3) Stabilization by heat transfer to a liquid (in-rotating-liquid spinning) (e.g., Allied Signal, Michelin, Unitika).
4) Solidification by direct contact with a moving-solid, heat-extracting surface. Although round fibers cannot be made by this technique, it was and still is the only one that has developed into a full-blown industrial process (Allied Signal, 1976). In this respect, it is the process responsible for the commercialization of amorphous metals (ribbons and sheets).

Figure 37. Taylor process for the production of metal fibers

Most of the processes failed to become fully industrial because they could not be upgraded from workable single-fiber processes to multi-fiber operations. The most promising method is the in-rotating liquid spinning, established in 1981 and the only method that enables fibers with circular cross sections to be manufactured in continuous lengths.

Improvements remain to be realized with respect to production costs (development of the multi-hole process), raw-material prices (up to 10 % boron), and some vital mechanical properties, especially torsion characteristics and fatigue behavior.

Melt Extraction. The melt extraction processes avoid the need for orifices because the molten metal is extracted from a melt by a wedge-shaped edge of a rotating disk: CME (crucible melt extraction) or PDME (pendant drop melt extraction), see Figure 38. The process was invented and developed by Battelle and exploited on an industrial scale by Fiber Technologies (U.K.).

Figure 38. Crucible melt extraction (CME) for the production of metal fibers.
a) V-edged wheel; b) Wiping wheel

4.1.3. Other Processes

Metal fibers have also been made by chemical vapor deposition, mechanical methods, and electrolytic procedures. Other less important methods include slurry drying, decomposition, and reduction; in-situ decomposition of inorganic and organic compounds; and physical vapor deposition.

Chemical Vapor Deposition (Whiskers). Metallic whiskers are generally made from the gas phase by decomposing a compound of the metal (e.g., pentacarbonyl iron). Whiskers of iron, copper, and tin have been manufactured.

Mechanical Methods. Mechanical shaving methods, similar to those for steelwool production can be used, starting from either wire or stacked thin foils. The fibers so produced have irregular cross sections, either triangular or rectangular with a surface roughness and poor mechanical properties. The shaving methods were im-

proved by the introduction of superimposed vibrations, which result in more homogeneous cross sections and properties.

Electrolytical Procedures. After carbonization, organic fibers can be coated by electrolysis to produce metal sheaths. The organic and carbon residues can also be decomposed to leave hollow fibers. Metal fibers of Ni, Cr, or Cu as well as their alloys, can be formed. Another process consists of depositing continuous fibers on a suitably grooved mandrel.

4.2. Bundle-Drawn Fibers

4.2.1. Form and Dimensions

Bundle-drawn fibers can be produced in the form of continuous bundles, broken bundles (slivers), cut fibers, spun yarns, threads, cables, web, sintered web, needle felt, filter media, etc. All these morphologies are obtained by textile industry-like operations combined with metallurgical techniques, processes, and methods. The fiber diameters depend to a large extent on the metallurgical and structural purity of the starting material (wire rod), itself a function of the alloying elements and the manufacturing and purification procedures during wire-rod production.

4.2.2. Composition

The following are typical alloys lending themselves to the bundle-drawn fiber manufacturing:

Stainless AISI 316L
Stainless AISI 302
Carpenter 20Cb3
Inconel 601
FeCrAlloy
Hastelloy X
Nichrome
titanium

Standard diameters are 4, 8, 12, and 22 µm (Fig. 39). Of course, larger diameters are possible, such as 40, 50, and even 100 µm. For some alloys 12 µm is the lower limit. For very pure alloys, fibers 2 µm and even finer are possible (Fig. 40).

Figure 39. Microphotographs of bundle-drawn metal fibers A) Scanning electron microscope (×1250) B) Optical microscope (×1100)
a) 22 µm; b) 12 µm; c) 8 µm; d) 4 µm

Figure 40. Very thin bundle-drawn metal fibers, diameter 2 µm (×625)

4.3. Uses

Anti-Static Applications. Since metal fibers are good electrical conductors, they were first used in anti-static carpeting to dissipate the static charges. Very soon the same principle was applied to clothing for medical use as well as for work with explosives or sensitive electronic components of instruments, followed by anti-static filterbags for use with explosive dusts [83]. Cast floors, e.g., as in operation rooms, are made sufficiently conductive to eliminate the possibility of sparks and electric discharges. The same also applies to bed linen for use with oxygen tents, etc.

Filter Media [84]. Filters are one of the most promising areas for the use of metal fibers, since the existing products, such as woven wire mesh and sintered metal powders, no longer fulfill all criteria:

1) Fine pore size from 20 µm to a few micrometers
2) Large permeability (4 – 10 times higher than at present)
3) High dirt holding capacity, therefore longer operational life (fourfold or more than at present)
4) Acceptable and competitive price in the application niches

Only sintered metal fiber filter media can satisfy these requirements successfully. The principal areas of metal fiber filter media applications include the following:

polymer fiber and foil manufacturing
hot gas filtration
aircraft fuel de-icing and filtration
filtration in the fields of hydraulics and robotics
fine chemicals and pharmaceuticals
crossflow filtration
generation of nuclear energy: gas cooled reactors, cooling
water condensate, elimination of radioactive aerosols from waste gas flows during emergencies

Sound Absorption. Sintered metal fiber sheets can be deployed as highly effective sound barriers under circumstances where other absorbers are inefficient, e.g., in high-temperature environments and at high-energy sound levels. This is particularly the case for aircraft and turbine noise reduction.

Gas Burner Panels and Tubes [85]. Highly porous sintered FeCrAlloy sheets and tubes produce an efficient radiant surface for burning natural gas. The advantages over the usual ceramic burners are improved life cycle, lower NO_x, better malleability, and sturdiness.

Thermal Insulation and Flame Arresting. The heat conductivity of porous metal fiber structures is comparable to that of an average quality glass fiber mat, and such products have solved high-temperature insulation problems such as those involving the exhaust gases of the space shuttle thrust rockets. These sintered metal fiber structures also make highly permeable, extremely efficient, versatile flame arrestors.

Medical Applications. Titanium fibers are bio-compatible and can consequently be applied as porous ingrowth materials for implants to evoke bone development in the pores, guaranteeing perfect fixing and load transmission. Stainless steel fibers can be used to reinforce dental bioglass.

Electromagnetic Interference (EMI) [86]. With the proliferation of electronic appliances and instruments in our daily life, electromagnetic interference must be controlled. More and more appliances are shielded against outside interference, as well as against creating interference themselves. Present-day housings for electronic devices are made from composite materials of polymer matrix and metal fibers. The presence of a low concentration of conductive metal fibers of the correct alloy, structure, diameter, and length give these casings a total attenuation of more than 80 dB, this without altering the other properties of the polymer matrix.

Radar Camouflage. As a special case of EMI, an amount of the correct metal fiber in radar camouflage netting that matches as closely as possible the absorption and reflection characteristics of radar waves for the environment has the effect of concealing an object. Structures containing metal fiber can be adjusted to vary from zero to almost 100 % reflection or absorption.

Microwave Detection. Every metallic fiber structure has a unique microwave signature, or fingerprint, that can be detected, registered, personalized, stored, and recognized. This feature can serve for the identification and verification of valuables, security papers, passports, credit cards, identification cards, etc.

High-Voltage Protection. The effect of the strong electromagnetic field on persons working on live high-tension lines can be harmful to their health. A protective suit made from cloth containing up to 25 % metal fibers acts as an efficient shield.

Capillary Uses. Since bundle-drawn metal fibers are finely grooved on their surfaces and form very fine tubes in between themselves, a fiber wick exhibits large capillary action. This effect is used in heat pipes, space technology, etc.

Other Uses. Many other uses are under consideration or are being developed. A few important ones should be mentioned: catalysts and catalyst carriers, heat-exchanger media, diffusion barriers, coalescing and demisting media, gas–liquid separator media, high-temperature seals, and the heating of textiles (e.g., curtains).

4.4. Manufacturers

There are presently three major metal fiber producers: Brunswick Corporation (U.S.A.), Nippon Seisen (Japan), and N.V. Bekaert (Belgium). Not all of them produce all the various qualities and shapes available; some are integrated into the endproducts. N.V. Bekaert S.A. makes the largest variety of alloys, diameters, half-products, and shapes, as company policy is not to be integrated.

4.5. Melt Spun Fibers

4.5.1. Properties

The quality and the properties of fibers produced by most melt extrusion processes are quite satisfactory, and this is particularly the case for the amorphous or microcrystalline fibers (Fig. 41). In addition to the somewhat unusual magnetic and physical properties of the fibers, tensile strengths up to 7000 N/mm^2 have been obtained. However, poor dynamic behavior (e.g., fatigue) is still a weakness. Equivalent diameters (generally the fibers are not round) range from 25 to 300 µm, depending on the process and the melt composition.

Producing continuous lengths by melt extraction has proved to be extremely difficult, but by notching the edge, short fibers and flakes with an equivalent diameter of 20 – 200 µm can be produced. Filaments with circular cross sections are not available commercially.

Figure 41. Surface of melt-extruded metal fiber, diameter ca. 0.36 µm (magnification ×250)

4.6. Uses

Melt Extrusion Fibers. If amorphous or microcrystalline fibers with circular cross section become commercially available, there would be an opening in those areas that already are served by amorphous ribbons: transformers and other electromagnetic equipment, shielding, sensors, etc. However, by far the biggest market would be for structural uses, especially in tire reinforcement, with a potential of $0.5 - 1.0 \times 10^6$ t/a.

Melt Extraction Fibers. Melt extraction fibers are mainly used for the reinforcement of concrete and, in particular, of refractory cements where they compete with conventionally drawn carbon and stainless steel wires. The smaller flakes also have some potential as fillers in polymers for electromagnetic interference applications, where they must compete with the bundle-drawn metal fibers.

Economic Aspects. Metal fiber prices are tending downwards as more and more high volume applications are being implemented.

5. Carbon Fibers

Carbon fibers are black fibers used as yarns, felt, or powderlike short monofilaments with diameters smaller than 10 µm. They are mainly

applied to reinforce polymers, much like glass fibers have been used for decades in fiber glass, with the principal difference that composites with carbon fibers are so-called *advanced composites* or *high-performance composite materials.* The progress achieved with carbon fibers, as compared with glass reinforcement fibers, is based on the superior stiffness of carbon fibers, combined with high strength and low density. As can be seen from Figure 42, the density of polyaramide fibers, introduced into the market nearly simultaneously with carbon fibers, is even lower, but strength and stiffness of these organic fibers do not reach near the top values for carbon fibers.

	Glass	Aramide	Carbon
ρ g/cm³	2.5	1.45	1.8 (2.1)
σ MPa	2000–4000	3000	3000–5000 (2000)
E ∥ GPa	50–80	70–130	200–500 (700)
ε %	4–5	2–4	0.5–1.9 (0.3–0.5)

Figure 42. Comparison of the reinforcing fibers for advanced composites with polymer matrix: glass, polyaramides, and carbon

Figure 43 shows the superior specific stiffness (Young's modulus measured in fiber direction divided by the density) of various types of carbon fibers in comparison with those of polyaramide and glass fibers. The extremely low values for isotropic conventional metals and the theoretical maximum for the anisotropic graphite single crystal are also included. This figure demonstrates not only the superiority of carbon fibers but also the variability of stiffness among the various carbon fiber types. In the best case, up to 80 % of the theoretical modules of a graphite layer can be realized in a commercial material.

Figure 43. Specific tensile modulus (Young's modulus divided by density) of the various carbon fiber types (PAN and MPP) in comparison to other structural materials
∗ = single crystal (a-direction)

Nomenclature. Terms for description of new materials should be based on scientific characterization. Trivial terms, introduced locally, and still used, should be avoided. In UK and France the term *carbon fiber* is used correctly. In USA, however, the scientifically unjustified term "graphite fiber" is preferred in industry, and in German, as well as in Eastern European languages, the tradition of describing carbon materials as coal has been carried over to the new material carbon fiber (German: *Kohlefaser*). The IUPAC has therefore established a sub-committee for description and characterization of carbon and graphite materials in general and of carbon fibers in specific. Some tentative recommendations for the terminology [87], partly still under discussion, are the following:

Carbon fibers are fibers (filaments, yarns, rowings) consisting of at least 92 wt % carbon, regularly in the nongraphitic stage, that is, with two-dimensional long-range order of the carbon atoms in planar hexagonal networks, but without any measurable crystallographic order in the third direction (c direction) apart from more or less parallel stacking.

HM-type carbon fibers are carbon fibers with a value of the modulus of elasticity in the fiber direction larger than 30 % of the elastic number c_{11} of a graphite single crystal, but with a ratio of tensile strength to tensile modulus below 1 %.

HT-type carbon fibers are carbon fibers with a value of the tensile strength above 3000 MPa and a ratio of strength to stiffness of ca. 1.5 – 2.0 %.

IM-type carbon fibers belong to the HT type carbon fibers because of comparable values of tensile strength but are characterized by improved stiffness (Young's modulus up to 30 % of the theoretical c_{11} value with remaining values of the ratio strength to modulus above 1 %).

In addition, the precursor material of the carbon fibers is important because the combination of various fiber properties and the behavior of the carbon fiber mechanically, physically, and chemically depend strongly on the raw material.

PAN-based carbon fibers are carbon fibers obtained from polyacrylonitrile (PAN) precursor fibers by stabilization treatment, carbonization, and possibly final heat treatment at even higher temperature.

Isotropic pitch-based carbon fibers are carbon fibers obtained from isotropic pitch fibers by stabilization treatment and carbonization.

Anisotropic pitch-based carbon fibers (MPP-based carbon fibers) are carbon fibers obtained from mesogenic pitch after this has been transformed into mesophase pitch (MPP) during the process of spinning, by stabilization of the spun mesophase pitch fibers, carbonization, and final heat treatment at even higher temperature.

Rayon-based carbon fibers are carbon fibers obtained from rayon precursor fibers by chemical pretreatment and carbonization. They are isotropic carbon fibers and can be transformed into anisotropic carbon fibers with high strength and stiffness by hot stretching above 2800 K.

Gas-phase grown carbon fibers are carbon fibers grown in a hydrocarbon atmosphere with the aid of fine particulated solid catalysts such as iron or another transition metals. They consist of graphitizable carbon and can be transformed into graphite fibers by heat treatment above 2800 K.

5.1. Properties

5.1.1. Mechanical Properties

The strength values differ dramatically among the various carbon fiber types. Because carbon fibers exhibit brittle fracture behavior, the strength: stiffness ratio strictly controls the fracture elongation (strain to failure) of the fibers. In Figure 44 these relationships are demonstrated graphically in three coordinates. The values of all commercially available carbon fibers are grouped around two areas, which describe opposing combinations of properties: the high modulus domains (HM-type fiber) and the high-strength, high-tenacity domains (HT-type fiber).

Figure 44. Characterization of the various commercial carbon fiber types by tensile strength and Young's modulus
HT = high tensile; IM = intermediate modulus; HM = high modulus; MPP = mesophase pitch-based high-modulus fibers

Nearly all carbon fibers available commercially have a near-circular cross section. As shown in Figure 45 (see next page) the cross section of the carbon fibers mirrors the fiber precursor. Currently (1986) wetspun PAN is usually the raw material. Gasphase-grown carbon fibers exhibit the best graphitic order and preferred orientation, but have no importance for reinforcement.

5.1.2. Chemical Composition

Carbon fibers consist of elemental carbon. As all synthetic carbon materials, they are fabricated from carbon compounds by thermal degradation (pyrolysis), and the final (i.e., maximum) heat-treatment temperature controls the nature and amount of remaining ligand atoms in the residual carbon. The HM-type fibers consist

Figure 45. Fracture surface of the precursor fibers (rayon, wetspun PAN, mesophase pitch) and of the resulting carbon fibers (REM)
Carbon yield given in wt %

of nearly pure carbon; however, the HT-types contain some nitrogen (<4 wt %) and oxygen (<1 wt %). Hydrogen contents can be neglected [88, 89].

Surface-treated carbon fibers contain, in addition, solid oxygen complexes on the surface and organic coatings (sizing), which protect the carbon fibers during handling and transport.

5.1.3. Structure

Solid elemental carbon has two equilibrium modifications: diamond with isotropic homopolar bonds between the carbon atoms and sp^3 hybridization of the electron levels and the hexagonal graphite with sp^2 hybridization, thus anisotropic structure. Rhombohedral graphite is a result of mechanical deformation of the hexagonal form. The broad variety of disordered carbons belongs to the graphitic modification mainly with sp^2 hybridization and thus a tendency to form planar polyaromatic molecules but with only two-dimensional order and no hexagonal ABAB-shaped arrangement of these polyaromatics in the third dimension. In this sense carbon fibers can be described as disordered carbon with more or less ordered polyaromatic layers and a hypermolecular anisotropic arrangement of these polyaromatics parallel to the fiber axis. Perfectness, size, and arrangement of these polyaromatics control the physical and especially the mechanical properties of the fibers. Partial sp^3 hybridization was confirmed in all artificial carbon, and especially in carbon fibers, and is explained by the carbon atoms on the edges and in disclinations of the polyaromatics [90, 91].

Figure 46. TEM bright field images (cut perpendicular to the fiber axis) [90, 92]
A) Typical commercial HT type (T 300) B) HM type (SIGRAFIL HM) carbon fiber

Transmission electron microscopy (TEM) produces bright field images of thin-layer cuttings of HT- and HM-type carbon and reveals the different degree of defect structure (Fig. 46) [90, 92].

The preferred orientation in the direction of the fiber axis as indicated by the Ruland parameter q (0 corresponds to a statistic arrangement and −1.0 means completely preferred orientation) is shown in Figure 47 [93]. Some experimental fiber types based on mesophase pitch reach nearly 100 % of the theoretical Young's modulus, i.e., that of a single crystal. Such a preferred orientation is combined, however, with the disadvantage of low shear resistivity.

The layer distance, which is easily measured, is a good indication of the degree of defect structure of a carbon fiber. Figure 48 shows the values for commercial fibers as received and the reduction of the $\bar{c}/2$ value by further heat treatment, which heals structural defects [94].

Figure 47. Young's modulus of the various types of carbon fibers correlated with the degree of preferred orientation measured by X-ray diffraction and expressed by the Ruland parameter [93]
0 = statistical distribution, 1.0 = orientation of graphite single crystal

Figure 48. Main interlayer distances $\bar{c}/2$ of various commercial carbon fibers and their decrease due to subsequent heat treatment. The $\bar{c}/2$ values of graphitizable petroleum coke are included for comparison [92, 94, 95]
a) Ideal graphite; b) Petroleum coke; c) P55, MPP-based; d) AS4, PAN-based; e) T300, PAN-based; f) T800, PAN-based

This healing process results in higher density and increased Young's modulus, which is shown in Figure 49B. The strength passes a maximum at heat-treatment temperatures around 1500 °C (Fig. 49A). The reduction of strength, with the minimum around 1800 °C, is caused by the escape of the remaining ligands, which causes severe structural disturbance. Only minor improvement takes place during further annealing. The variety of curves for PAN-based fibers is caused by differing oxidative pretreatment during the stabilization before carbonization [96, 137].

Figure 50 (see next page) shows the effects on the ultrastructure of heat treatment. The ordering process at the highest temperatures is easy to recognize for a commercial HT fiber by the enlargement of domains with parallel layer stacking (Figs. A and B). Such improvement of strength by annealing is not found in the case of pitch-based fibers with superior preferred orientation because of increased shear sensibility by annealing (Figs. 50 C and D). The much higher tendency of mesophase pitch-based fiber towards structural rearrangement can also be seen in Figure 50.

Based on electron microscopic studies, several models for structure in carbon fibers have been proposed. Four of these are shown in Figure 51 [97–99]. In all cases, parallel stackings of polyaromatic layers are arranged in the fiber direction in forms such as ribbons,

Figure 49. The effects of heat posttreatment of carbon fibers [96, 137]

plates, hoses, tubes, or combinations of the various structural elements.

5.1.4. Physical Properties

Table 16 shows the densities, electrical resistivities, thermoelectric powers (TEP), magnetic susceptibilities, heat capacities, and thermal conductivities of the various carbon fiber types.

The reversible thermal expansion is highly anisotropic (Table 17). In PAN-based HT-type carbon fibers high anisotropy is also found, as is the case for graphite single crystals. In contrast, the reported anisotropy in a mesophase pitch-based HM-type fiber is much smaller [100]. Experimental measurement for the direction perpendicular to the fiber axis, however, is very difficult, and a comprehensive study is still not available.

Table 17. Reversible thermal expansion of some commercially available carbon fibers.

	CTE $\alpha_{\parallel}$, 10^{-6} K^{-1}	CTE $\alpha_{\perp}$, 10^{-6} K^{-1}	$-\alpha_{\perp}/\alpha_{\parallel}-$
Graphite, single crystal	0.5 – 1.0	29	29 – 58

chemicals at ambient temperatures is well-known and has been utilized in chemical apparatus. The behavior of carbon fibers is similar. Only fluorine acids as well as strong oxidants attack carbon fibers strongly. The tendency of graphite to form intercalation compounds with halogens, salts, oxidizing acids, and some other substances is also well-known. The majority of carbon fibers, which consist of nongraphitizable carbon is less susceptible to intercalation attack. Only gasphase grown fibers can be intercalated easily.

Most destructive for carbon fibers are their reactivity with metals, above all aluminum at temperatures below 1000 K, and their reactivity with solid oxides at temperatures above 1000 K. This reactivity limits the use of uncoated carbon fibers for reinforcement of metals and oxides. However, if reaction and diffusion barriers are built in – silicon carbide, titanium nitride, and similar coatings have proved to be successful barriers (Fig. 52) –carbon fibers can be used to reinforce metals and oxides [101, 102].

Figure 52. SiC-coated carbon fibers in a SiO_2 glass matrix (parallel to the fibers) [101]

Figure 53. Oxide complexes on surface-treated carbon fibers and their affinity to polar groups in epoxy resins and curing agents [103]

Solid surface oxides form as an intermediate stage before formation of volatile carbon oxides. Such solid surface oxide complexes improve the adhesion of carbon fibers in polymers and matrix in a composite [105, 106]. The thermal stability of surface oxides is limited to temperatures below 800 K for carboxylic groups and below 1000 K for nonacidic surface oxides. Figure 53 [103] shows the various types of surface oxides and their affinity to polar groups in the resins, which initiates at least chemisorptive adhesion and perhaps even formation of extensive chemical bonding between fiber and resin.

The degree of adhesion is measured by interlaminar shear strength (Ilss). Figure 54 shows the effect of stepwise desorption of the surface

Figure 54. Gases (CO_2, CO) liberated during thermal desorption of surface-treated carbon fibers [89]

oxides in surface-treated carbon fibers by heat treatment in argon and the resulting effects of such stepwise desorption on the remaining adhesion in an expoxy matrix. The strong improvement of adhesion in surface-treated HM fibers is associated with the carboxylic groups. The improvement of adhesion in HT-type fibers by surface treatment is much smaller, a maximum of 30 % of the total adhesion. The remaining adhesion in HT-type fibers is strongly correlated with the nitrogen content in the fiber. The adhesion of the fibers decreases abruptly if they are heat-treated above 1200 °C, which drives off the nitrogen remaining from the PAN precursor [88].

The controlled formation of surface oxides can be attained by three routes:

1) Thermal oxidation at temperatures above 700 K
2) Wet oxidation in boiling nitric acid or in a similar oxidative liquid
3) Anodic oxidation in aqueous solution

Anodic oxidation is the only method used industrially for surface oxidation of carbon fibers. This process is the easiest to control and forms the greatest amount of surface oxides (Fig. 55).

Figure 55. Amount of surface oxides formed by thermal, wet, and anodic surface treatment of HM fibers as measured by weight loss during thermal desorption in argon [104]
a) Thermal oxidation; b) in HNO_3 oxidized; c) anodic oxidation

Thermal oxidation, although simple to do, is dangerous because of the rapid reaction rate and the danger of fiber damage due to total oxidation. Figure 56 shows in an Arrhenius plot the experimental weight loss on oxidation of carbon fibers in air [104]. The HT-type fiber, which is given a maximum heat treatment at 1450 °C during fabrication, is much more sensitive to total oxidation than the HM-type fibers, which are heat treated above 2500 °C during fabrication. Total oxidation can be catalyzed even by alkali-metal compounds, as is the case for carbon and graphite materials. Heavy metal oxides are effective catalysts. Experimental results on the effect of copper oxide and vanadium oxide on the relatively resistant HM-type fibers are included in Figure 56. As a consequence, metallic impurities in carbon fibers have to be strictly avoided during industrial production.

5.2. History

Public disclosures of practical processes for converting textile fibers into useful carbon fibers have been confined largely to the patent literature.

5.2.1. Rayon-Based Carbon Fibers

For rayon as the precursor material, a comprehensive survey was published by R. Bacon [107]. One hundred years ago, Edison [108] described an incandescent-lamp filament made by carbonizing a filament of natural and regenerated cellulose material. In the 1950s Abbott [109] developed a process for converting

rayon into a fibrous carbon material for insulation, filtration, and absorption. This material was carbonized at temperatures up to 1000 °C and possessed tensile strengths of only 280 MPa. In 1959, Union Carbide [110–112] started commercial production of similar fibers, and other companies in the U.S.A. followed.

Various fiber types heat-treated at final temperatures around 1200, 1800, and even above 2500 °C have become commercially available, e.g., the carbonized VIB type and the WYB type heat-treated at graphitization temperatures, both from UCC (Union Carbide). The tensile strength of such fibers ranged from 300 to 700 MPa, while their moduli were between 30 and 50 GPa. The most important application was the reinforcement of phenolic resins to form ablative materials for rocket and missile components. This early period of carbon fiber production and application is reviewed by Schmidt and Hawkins [113].

In these first years of the carbon fiber industry, several companies introduced a pretreatment process for the precursor fibers to increase carbon yields and speed up the processing rates, especially in the early heat treatment stage. The Pluton fiber of 3 M [114] was introduced in 1961. A decisive improvement of the mechanical properties of the carbon fibers was the plastic deformation of the fibers at temperatures above 2500 °C. This UCC process [115] led to the commercial production of the Thornell type, which had in 1965 a tensile strength of 1260 MPa and a modulus of 175 GPa (Thornell 25).

This was the period when the US Air Force Material Laboratory in Dayton, Ohio, strongly supported further development in the field of high-modulus carbon fibers [116, 117]. The goal was to replace boron fibers as soon as it proved possible to fabricate high-performance carbon fibers with a minimum modulus of 350 GPa. In 1970, UCC reached the goal with the commercially available Thornell 75 HM-type carbon fiber, which also had a Young's modulus of 500 GPa, a value corresponding to 50 % of the theoretical c_{11} value. Hitco [118] entered the market with yarns produced by similar methods. Although these carbon fibers were satisfactory in applications, the final decision of the market was to restrict use to the PAN-based carbon fibers.

5.2.2. PAN-Based Carbon Fibers

The history of PAN-based carbon fibers starts in 1950 with the observation of R. C. Houtz [119] that polyacrylonitrile fibers are converted into black, flameproof materials by heat treatment at 300 °C in air. However, products produced by this method were not used before 1959 [120]. At that time the discovery was made that flexible, flameproof textiles with the original fiber structure can be obtained only if the exothermic reaction between 150 and 300 °C is strictly controlled and if the high shrinkage during this thermal treatment is minimized by mechanical means. In 1960 the process to produce a flameproof fiber, starting with Dupont's AF Orlon fiber and commercialized as Black Orlon, was described in detail by Vosburgh [121]. Heat treatment up to 15 h at 220 °C was needed to produce a well stabilized fiber with a strength of 40 % of the value of the original PAN fiber. The oxygen content of the final product was 10 – 20 wt %.

Surprisingly, this oxidizing-blackening treatment of the PAN fibers was not complemented by carbonization. Such a combination was first claimed by Shindo [120] in 1959. A maximum tensile strength of 100 MPa was obtained. In 1965, Johnson, Philip, Watts [122] added to this combined process the need to restrain shrinkage or alternatively to stretch the PAN fiber during stabilization treatment. They obtained carbon fibers with Young's moduli up to 420 GPa. This process is now the standard process for fabrication of PAN-based carbon fibers, although patent protection turned out to be limited and is completely gone today. A more detailed history is given by Watts [123], and a complete literature survey is given by D. J. Mueller [124].

5.2.3. Pitch-Based Carbon Fibers

The processes for carbon fibers from pitches are based on the observation of Otani [125] in 1963 that some pitches are spinnable to pitch fibers, which can be converted into carbon fibers. Pitch from poly(vinyl chloride) turned out to be the best, but a variety of other pitches can be used after specified pretreatment as summarized by Sugio Otani and Asao Oya [126]. The mechanical properties of the resulting carbon fibers were

in the range 800 – 1800 MPa for tensile strength and 20 – 50 GPa for Young's modulus. These pitch-based carbon fibers were commercialized in 1970 by Kureha Chemical Industries and are still the only ones commercially available in the form of continuous yarns [127]. In 1985, FREEMAN [128] reported that the Ashland Company started production of a variety of carbon fiber types using petroleum pitch as the raw material. Coal tar pitch is recommended as an alternative precursor material by ROMMEY [129]. All these pitch-based carbon fibers belong to the isotropic, low-modulus type.

Fabrication of anisotropic pitch-based carbon fibers with greatly improved mechanical properties was achieved by LEWIS and SINGER et al. [130] in 1976. This process is based on the mesophase, a liquid crystal formed within the pitch before spinning that enables the formation of a preferred orientation in the pitch fiber, thus also in the final carbon fiber. Values of tensile strength up to 3000 MPa and an extremely high Young's modulus, up to 600 GPa, can be achieved.

Laboratory developments have continued in many countries of the Western World. Commercial products are available from AMOCO (previously Union Carbide) [131].

5.2.4. Vapor-Grown Carbon Fibers

Whiskers and needles of carbon deposited from the gas phase were described in 1966 by FITZER and SCHLESINGER [132]. FITZER and RHEE [133] continued these studies and reported in 1970 growth rates and mechanical properties of the whiskers and needles. Tensile strengths up to 1500 MPa and stiffness values up to 300 GPa were reported. The decisive progress was reported by ENDO [134] in 1974 when he recognized that the whisker growth follows a catalytic mechanism starting from fine, dispersed solid metal particles in the substrate. Whisker lengths up to 250 mm and tensile strength values up to 26 000 MPa have been reported so far by ENDO [134]. Commercialization has not been announced, however, probably because of the completely different structure of vapor-grown carbon fibers. These consist of soft carbon, that is, the graphitizable less-disordered variety. Therefore, high mechanical properties cannot be expected. They are most suitable for intercalation (high electrical conductivity).

5.3. Production

All commercial production processes for carbon fibers are based on carbonization of polymer fiber precursors. The preconditions for useful fiber formation compiled in Table 18 must be fulfilled. Thus, the number of suitable polymer fibers is limited. The fiber form is always preserved during carbonization in the case of nonmeltable polymers, such as thermosetting resins, which can be thermally degradated directly. Thermoplastic precursor fibers have to be converted into a nonmeltable form before carbonization. This is called stabilization treatment and occurs on conversion of the linear polymers into ladder polymers and on formation of additional cross-linkages. In the case of pitch precursor fibers, the melting of the mixture of polyaromatic compounds must be hindered by oxidation. Three precursor materials are satisfactory: (1) rayon fibers, (2) PAN fibers, and (3) pitch fibers. Rayon fibers do not require stabilization, only preimpregnation is necessary to improve the carbon yield. PAN and pitch fibers need sta-

Table 18. Restrictions on the precursor fiber for carbon fiber fabrication

Preconditions for carbon fiber manufacture	Parameters	
	Precursor	Process
Preservation of the fiber form of the polymer	thermosetting or thermoplast fibers	direct thermal degradation or stabilization treatment of meltable precursor before thermal degradation
High carbon yield	selection of the polymers	optimization of the stabilization and carbonization parameters
Preferred orientation of the polycarbon layers with highest degree of defects in the ultra structure	highly cross-linked, unmeltable polymers	stretching of the precursor before or during stabilization and/or hot-stretching of the carbon fiber

bilizing pretreatment. The carbon yield is lowest for rayon fibers and highest for stabilized pitch fibers:

Rayon fibers	25 %
Oxidized pitch fibers	80 %
Polyacrylonitrile	50 %
Oxidized pitch	up to 80 %
Phenolic and furan resins	up to 85 %

The most important parameter in producing high-quality carbon fibers is the preferred orientation of the polyaromatic layers parallel to the carbon fiber axis. Only then can the high strength of the bonds in the molecular structure of the graphite lattice (c_{11}= 1060 GPa, c_{33}= 33 GPa) be transferred into stiffness and strength of the carbon fiber. The low shear modulus in the graphite crystal structure (c_{44}= 4.6 GPa) must be avoided by having the highest degree of defects in the ultrastructure of the carbon fiber. In the case of rayon precursor fibers the needed high degree of structural imperfectness can be realized, however the preferred orientation is realizable only by hot working of the carbon fiber at 3000 K. This hot stretching process is difficult to carry out on an industrial scale. Therefore, carbon fibers are no longer produced from rayon.

In PAN- and pitch-based anisotropic carbon fibers, the preferred orientation is introduced into the precursor before carbonization. Polyacrylonitrile is the most important precursor material. More than 90 % of all commercially produced carbon fibers that are used for reinforcement of polymer material are based on this polymer. Only a minor part is produced from pitch.

5.3.1. PAN Precursor Fiber

Textile PAN fibers usually consist of ternary mixtures of copolymers with 89 – 95 wt % acrylonitrile (AN), 4 – 10 wt % of a non-ionogenic comonomer plasticizer, and 1 wt % of additive to chemically bond dyes [135]. For the precursors for carbon fibers, a lower content of comonomers, usually below 3 wt %, is used.

Figure 57. The chemistry of stabilization and carbonization: fabrication from homopolymer PAN and stabilized PAN [137, 138, 147]

Polymer fibers can be spun by melt, wet, and dry spinning processes. In the case of polyacrylonitrile as a carbon fiber precursor, the wet spinning process is the most important. In 1986 a new melt spinning process was presented which would offer economic advantages [136].

The solvents dimethylformamide (DMF) and dimethylacetamide (DMA) are usually preferred for wet spinning today. For carbon fiber precursors, however, the inorganic solvents nitric acid, stannum chloride and thiocyanate are also used. In any case, copolymer composition of the precursor, the spinning technology, and especially the solvent are almost always strict commercial secrets. Only Courtaulds (United Kingdom) describes the use of dimethyl sulfoxide for fiber precursor fabrication.

The main difference between textile PAN fibers and PAN precursor fibers is the different degree of stretching: the stretching ratio for textile fibers is 1 : 2 to 1 : 10, that for PAN precursor fiber 1 : 12 or more. There is the danger of overstretching, which introduces defects into the polymer fiber that initiate defects in the carbon fibers, thus causing low strength.

The extremely high-strength and high-tenacity carbon fibers are mainly produced from precursors more carefully spun and stretched to a higher degree. Dry-jet wet spinning would be a good method for this.

5.3.2. Stabilization

Polyacrylonitrile is a thermoplastic polymer that decomposes above 370 °C. A suitable stabilization process is needed before carbonization to obtain an infusible intermediate that preserves the orginal fiber structure. This intermediate is known as inflammable textile (e.g., PAN-Ox).

The stabilization step is the most important one from the viewpoint of carbon fiber quality and process economy. The reaction is diffusion controlled, and a residence time of ca. 1 h at temperatures between 200 and 280 °C is needed. Fiber shrinkage during stabilization must be avoided (see Section5.2.2).

The chemistry of the stabilization process is illustrated schematically in Figure 57 (see previous page). The thermoplastic chain is cyclized to a naphthyridine ring system and simultaneously dehydrated in the backbone to form conjugated double bonds. The resulting aromatic polymer has ladder units of about five, corresponding to the average number of isotactic sequences in the nitrile polymer. Cyclization can occur with or without simultaneous dehydrogenation as shown in Figure 58 [137]. In both cases strong exothermic reactions are observed. In industrial processes, cyclization is always carried out in an oxidizing atmosphere because of the much higher carbon yield during the subsequent carbonization [139].

Figure 58. The exothermic stabilization in nitrogen (cyclization) and in air (cyclization and dehydrogenation) as revealed by DSC (differential scanning calorimetry) [137]

There is a direct correlation between the amount of oxygen absorbed and the density of the stabilized fiber. The best mechanical properties result for a precursor density of 1.4 – 1.42 g/cm^3, which corresponds to oxygen contents of 10 – 14 wt % (Fig. 59).

The stabilization causes the color to change from the white of polyacrylonitrile to yellow

and brown and finally to the black of the intermediate, the oxidized, inflammable polyacrylonitrile. The stabilization chemistry has been treated comprehensively in numerous papers, e.g., [137, 138, 140–147].

Figure 59. The effect of oxygen uptake during stabilization on the strength of the final carbon fiber
a) 230 °C isotherm/air; b) 230 °C isotherm, 1st stage N_2, 2nd stage air; c) 230 → 270 °C nonisotherm/air

5.3.3. Process Parameters

The carbonization step can be carried out much faster than the stabilization step; however, the evolution of the volatile byproducts, mostly H_2O, HCN, CO_2, and N_2, must be taken into account [148].

Practical temperature – time profiles have been published [137, 142, 149–151]. The quality of the final carbon fiber product is controlled by the precursor fiber, the stabilization treatment and the oxygen content, and finally by the carbonization schedule.

An example of a continuous stabilization and carbonization for fabrication of carbon cloth from PAN from patent literature is shown in Figure 60 [152].

5.4. The Pitch Fiber Process

5.4.1. Isotropic and Anisotropic Pitch Fiber Precursors

Carbon fibers made from pitch precursor are available with isotropic or anisotropic structure, the former made from isotropic pitch, the later from mesophase pitch. The isotropic pitch-based carbon fibers have low mechanical properties. They have been produced industrially from coal tar pitch by Kureha (Japan), for more than 15 years. The petroleum pitch producer Ashland (United States) manufactures isotropic carbon fibers, which are used mostly for thermal and mechanical insulation but also as fillers.

Anisotropic carbon fibers, which can be used for reinforcement because of their excellent mechanical properties, are produced in a process that takes advantage of the larger planar polyaromatic molecules in pitch and their tendency to form liquid crystals with parallel polyaromatic layers. The mesophase pitch is melt spun and stretched in the plastic deformable stage to produce pitch fibers with preferred orientation.

Figure 60. Hitco process for production of carbon cloth from PAN cloth showing temperature and tension profiles [152]

Figure 61. The coalescence of discotic liquid crystals in pitch

All pitch fibers must be stabilized before carbonization, but pitch fibers with preferred orientation consisting to a large extent of mesophase not only hinder melting during carbonization but also cross-link the polyaromatics upon oxidation thus hindering formation of graphitized carbon fibers.

5.4.2. The Mesophase Formation

Pitch is the residue from distillation of coal tar or crude oil or from cracking hydrocarbons. All pitches consist of thousands of aromatic hydrocarbons along with more or less cyclic aliphatics and aliphatic side chains. The molecular mass of the polyaromatic compounds ranges between 200 and 800. All the compounds in a single pitch have never been identified. Pitches are characterized by fractionation: their solubility in a sequence of standard solvents (Table 19). The model molecules shown in the table are suggested by comprehensive analytical investigations [153]. The melting points of the various pure compounds cover a range of hundreds of degrees. Pitches, however, form multi-eutectic systems with softening temperatures between 50 and 300 °C, much lower than the melting temperatures of the pure aromatic components.

The mesophase is formed during thermal degradation in the temperature range 400–450 °C and is controlled by the hydrogen content remaining in the aromatics during this heat treatment. Aromatics with an average molecular mass around 800 (coal tar pitches) and aromatics with aliphatic side chains and a molecular mass around 1000 (petroleum pitches) are able to form nuclei for discotic liquid crystals [153].

The liquid crystals in pitch are spherical with the molecular orientation shown in Figure 61. The coalescence of these liquid crystals with disklike molecules is similar to that of the liquid crystals with rodlike molecules.

From the viewpoint of the phenomenology, the formation of liquid crystals is similar to that of crystallization, starting from observable nuclei with diameters larger than 1 μm. The growth and coalescence proceed until all isotropic pitch matrix is consumed. Insoluble impurities in the molten pitch matrix (primarily quinoline insolubles, i.e., the pitch residue) inhibit coalescence and therefore also the formation of large volumes of anisotropy.

5.4.3. Process Steps

The viscosity of pitch, a precondition for satisfactory melt-spinning behavior, is determined by pitch composition. Figure 62 shows the apparent viscosities of a typical petroleum pitch and a typical coal tar pitch as functions of heat treatment [154]. The behavior of toluene-soluble (TS) and toluene-insoluble (TI) fractions of the coal tar pitch and of two mixtures of TS and TI fractions are included. Softening of the pitches upon heating is indicated by viscosity decrease; solidification due to mesophase formation, by viscosity increase. Spinning is difficult for

Table 19. Characterization of typical coal tar and petroleum pitches by solvent fraction and model molecular structures for the fractions [153]

high mesophase contents (which produce the HM fibers), however carbon yield increases with viscosity (Fig. 63) [154]. These contradicting conditions cause technological problems.

a) Toluene soluble; b) SP80 and 4 : 1 mixture; c) 1 : 1 mixture; d) 1 : 4 mixture; e) 1 : 9 mixture; f) toluene insoluble

Stabilization is carried out between 200 and 300 °C [155], much like in the PAN process. The stabilization times are dramatically shorter, however, between 10 and 30 min. The patent literature indicates that commercial pitch-based carbon fibers are given a final heat treatment around 1800 °C (P55 type). Fiber types with a relatively high Young's modulus, in the area of 400 GPa, can be achieved (cf. Fig. 44). A flow sheet for the entire fabrication process is given in Figure 64 [156].

Figure 64. Flow sheet for manufacture of carbon fibers from pitch (Union Carbide Corp. (UCC) process) [156]

5.5. Comparison of the Carbon FibersBased on PAN and on Pitch

Figure 65 shows the stress – strain behavior of PAN-based carbon fibers, as commercially available, of the intermediate modulus fibers in development, and of isotropic and anisotropic pitch-based fibers.

Figure 65. Stress – strain behavior of commercially available PAN- and pitch-based carbon fibers

The pitch process for carbon fibers potentially offers the capacity to produce carbon fibers covering the whole mechanical property range of the carbon fiber family. However, these expectations for pitch-based fibers have not yet been realized in spite of worldwide, intensive research.

The overwhelming part of commercial carbon fibers is the PAN-based HT type. High strain-to-failure of the fibers is seen as one of the key properties for the fracture toughness needed for broader application of advanced composites. The best strain values, between 1.5 and 2 %, are possible on industrial scale only with PAN-based HT-type fibers. Further, manufacturing problems are reduced if fabrication starts from a fully synthetic precursor material, with strictly controlled quality, instead of from a semi-natural raw material, such as petroleum or coal tar pitches, with strongly varying compositions depending on crude or coal type and the thermal history.

The applications of ultrahigh modulus carbon fibers from anisotropic pitch will most likely remain restricted to space structures and to carbon fiber-reinforced carbon fiber material (carbon – carbon composites). The challenge to increase the applications of anisotropic pitchbased carbon fibers can be satisfied only if production of medium-quality fiber types can be coupled with further drastic price reductions.

5.6. Commercial Availability and Economic Aspects

5.6.1. Companies and Trade Names

In the 1960s, the industrial production of carbon fibers started in UK, Germany, Japan, and USA with a total volume below 1000 t/a. Very soon, however, Japan had the advantage because of the availability of PAN-fiber plants using the wet process, whereas in USA and Germany PAN was produced mostly by the older dry process. Two Japanese companies specializing in the production of synthetic fibers, namely Toray and Toho Beslon, have succeeded in greatly expanding carbon fiber production. Today, these two companies dominate the world's carbon fiber production by licenses and joint ventures.

Hercules (USA) is independent from the two Japanese companies, but works jointly with Sumitomo, another Japanese PAN-precursor producer. Courtaulds fabricates precursors and is thus independent from Japanese imports. It is also the only company that sells PAN-precursor fibers suitable for a carbon fiber manufacture the world over without the limitations of licenses or joint ventures. In Germany, Sigri is independent, but fabricates no precursors. The producers, their production, their trade names, and some commercially available carbon fiber types from PAN precursors are compiled in Table 20.

5.6.2. World Capacity

The world capacity to produce carbon fibers is estimated to exceed 5000 t/a, and is increasing rapidly. The development of world production capacity during the last 15 years is shown in Figure 66. The small quantities of anisotropic and

isotropic pitch-based carbon fibers are included. There is disequilibrium between capacity, production, and real consumption, but more exact information is not available. It is estimated that capacity will grow up to 10 000 t/a and increase between 30 and 50 % per year.

Figure 66. World production capacity for carbon fibers

Average prices of carbon fibers are shown in Figure 67. The price for PAN-based carbon fibers strongly depends on the number of filaments in one tow. The so-called low-filament tows, with 3000 monofilaments, have been used for years. Currently (mid-1980s) most prepregs use tows with 6000 monofilaments. The tendency is to try to increase the filament number up to 12 000.

Figure 67. The development of carbon fiber prices

PAN-multifilament tows are the cheapest form of PAN-based carbon fibers: continuous 320 000 monofilament tows as used in textile application are difficult to handle in high-performance composites. They are mainly used for cutting into chopped fibers. However, multifilament tows with only 40 000 monofilaments have been introduced. The technological gap between the low filament tows (12 K and increasing) and the multifilament tows (40 K and decreasing) is diminishing. This should result in lower prices.

The price situation for anisotropic pitch-based carbon fibers is complicated. Around 1981 Union Carbide started to produce high-quality carbon fibers and sell them at $ 20 per kg, much below the price of PAN-based fibers at that time. As shown in Figure 67, the market situation and production difficulties forced the producer in 1983 to more than double the price. Anisotropic pitch-based high-modulus fibers are now much more expensive than PAN-based HT fibers.

The price situation is stable for isotropic pitch-based carbon fibers as delivered by Kureha for decades. Ashland, the Major petroleum pitch producer, has entered the market.

5.7. Future Importance

As has become evident over the last decade, polymers reinforced with carbon fibers present the opportunity not only to replace but also to displace structural metals [157]. The advanced composites (carbon fiber-reinforced plastics, CFRPs) are superior to conventional metals in respect to strength, stiffness, lightness, thermal expansion, fatigue, and corrosion resistance (Fig. 68).

Comparable Costs. The comparable costs of strength and stiffness of a unit volume of an advanced composite reinforced with PAN-based HT or HM carbon fibers, polyaramide fibers, glass fibers, former boron, or silicon carbide fibers have been estimated and compiled in Table 21.

From the viewpoint of strength, the glass fiber reinforcement is cheapest, followed by polyaramide and PAN-based HT fibers. PAN-based HM fibers are much more expensive. The CVD boron and silicon carbide fibers cannot be considered on an economical basis. From the viewpoint of stiffness, the carbon fiber-reinforced composites, although attractive on a price basis, are limited to the low modulus range.

Figure 68. The technical advantages of CFRPs over conventional metals

Table 21. The price related to specific tensile strength and specific stiffness.

Fiber type	Price, DM/kg	Density, 10^3 kg/m^3	Price divided by specific	
			Tensile strength, DM/ 10^4 kgm	Young's modulus, DM/ 10^4 kgm
E glass	10	2.50	1.5	0.07
Kevlar	40	1.45	2	0.05
C_{PAN} (HT)	70	1.75	3	0.05
C_{MPP}	200	1.99	17.5	0.19
C_{PHN} (HM)	450	1.85	27	0.30
B/c	1000	2.50	67	0.50
SiC/c	4000	3.50	400	3

Technological Fields. The aerospace field can expect the highest technical and economic benefit from application of these new materials. In the past such risky innovations were the only chance to realize some ambitious projects. The U.S. space shuttle is the best example. Although NASA designed this shuttle in the early 1970s essentially in conventional materials, it was not realizable without carbon fiber-reinforced doors for the loading room. In this way, carbon fiber-reinforced epoxies were tested in practice and accepted as performing structural materials for primary structures in manned flying vehicles. Today, military aircraft contain up to 50 wt % carbon-reinforced resins instead of light metals like aluminum. Commercial aircrafts are following step by step to replace aluminum by carbon fiber-reinforced composites.

The cost-benefit schedule of typical composite applications is:

space market	5 000 €/kg
air craft	500 €/kg
racing car	50 €/kg
automotives	up to 5 €/kg

The present calculation gives load savings of 15 – 30 % in aircraft and component costs of 77 – 150 €/kg. In automotives, load savings of 20 – 50 % but component costs up to 2.6 €/kg. Although the cost-benefit ratio is lowest in automotive applications, this field is the most promising for the future. To produce large cars with extremely light weight using the design rules of the aerospace industry presents a real challenge to the auto industry. The question becomes more and more a question of economy of scale for the fiber production on the one hand, and of rationalized processing for final products on the other. Plans for future production lines have already been published [158].

Another argument supporting a shift from metals to carbon fiber-reinforced composites is the energy requirements shown in Table 22

[159]. The numbers in the table include both the energy needed to process the materials and to process the raw material. The composites appear advantageous in terms of volumes and even more so in terms of mechanical properties per unit volume.

Table 22. Energy requirement in kWh for the production of Al, Fe, CFRP's and PVC [159].

Material	Density, $\frac{g}{cm^3}$	Energy requirement for production		
		$\frac{kWh}{kg}$	$\frac{kWh}{L}$	$\frac{kWh}{L} / \frac{N}{mm^2}$
Al	2.8	37.3	104.5	232.2
Fe	7.9	6.8	53.6	26.8
CFRP (UD)	1.5	3.7	5.6	3.5
CFRP (2D)	1.5	3.7	5.6	6.9
PVC	1.4	7.9	11.1	1110.0

6. Refractory Ceramic Fibers

High-purity aluminosilicate wool fibers, essentially free from group 1 and group 2 oxides, are melt-spun from calcined kaolin or pure alumina and silica mixtures in a fashion similar to that for glass wool, rock wool, and mineral wool fibers (see Chap. 2). Five compositions are in common use: 50/50 wt % alumina/silica (maximum use temperature of 1250 °C), 60/40 wt % alumina/silica (maximum use temperature of 1400 °C), and chromia-, boria-, or zirconia-modified 50/50 wt % alumina/silica (also for use at 1400 °C). The physical properties of the fibers are mainly determined by their diameters. most products have a weight mean diameter in the range of 2 – 3 µm.

Further details concerning production technology and composition can be found in [160]. The principle use of such fibers is for hot-face insulation of pottery kilns and metal-working furnaces. Production in Europe is of the order of 16 000 t/a. Correspondingly large amounts are manufactured in the USA and in Japan. Worldwide, the major manufacturers are the Morganite Group (USA, Japan, UK, FRG), the Carborundum Group (USA and FRG), and the Société Européenne des Produits Réfractaires (SEPR) in France [161].

The fibers are manufactured as a low density blanket (64 –96 kg/m^3), which is flexible and can be used as such. Alternatively, rigid boards and shapes can be created by vacuum-forming wet slurries of raw fibers and a refractory binder (usually a silica sol). Products can be designed to be dimensionally-stable and to have excellent low thermal conductivity up to 1500 °C when combined with high-alumina products such as ICI "Saffil" alumina (see Section 3.4.1) Rigid boards lend themselves to modular furnace designs with rapid heating and cooling cycles or where high gas velocities would lead to erosion of blankets. In all cases, the use of low-density fiber aggregates leads to significant energy savings in batch firing regimes compared to furnace designs employing dense refractories.

1. Introduction

1.1. History and Current State of the Art

For as long as textile fibers have been used, people have tested them in one way or another usually aided by nothing more than their eyes, their fingers, and occasionally, their noses. Visual methods, in refined form, are still in use today, generally because objective methods of measurement are lacking or are very expensive. Visual test methods are subjective and require great experience on the part of the person making the test.

Over the past decades, various methods of measurement and appropriate test apparatus have been developed for measurement of individual fibers. Such measurements presume great care, intuition, and skill on the part of the individual; nevertheless, the tester usually influences the results. Many individual values must be obtained because of the relatively high dispersion of fiber characteristics and properties; hence, measurements are tedious and costly.

Current developments tend toward so-called collective testing procedures which, together with automation and the use of computers, provide information on fiber properties very rapidly and minimize the influence of the individual tester. Frequently, the required properties themselves are not measured, but others that correlate with them. By coupling several testing devices, so-called test beds (high-volume testing, high-volume instruments) are created. This technology is still evolving.

1.2. Definitions and Basic Terms

Fibers are linear products that can be processed on textile machinery. Their common characteristic is a relatively high ratio of length to cross section, sufficient strength, and flexibility. Depending on their origin or composition, they are divided into the following groups:

1) Natural fibers (vegetable, animal, and mineral)
2) Man-made fibers from natural or synthetic polymers
3) Industrially produced fibers based on inorganic substances

Depending on their form, fibers are designated as

1) Staple fibers (fibers of limited length)
2) Filaments (fibers of practically unlimited length)

Test methods can sometimes be used with all kinds of fibers and sometimes only with certain kinds. In addition, methods are available for measuring characteristics specific to fiber type.

1.3. Test Procedures, Rules, Standards

To assure comparable and reproducible results, various organizations issue test procedures, rules, and standards. The following are some of the most important ones.

International standards and rules:

ISO International Organization for Standardization
EN European Standards
BISFA International Bureau for the Standardization of Man-Made Fibers
IWTO International Wool Textile Organization

Some national standards:

ASTM United States
AATCC United States
DIN Germany
BS United Kingdom
NF France

Standards or rules do not exist for all test methods. In that case, measurements are carried out according to methods developed by companies, institutes, associations, or instrument manufacturers.

Any existing standards or rules promulgated by ISO, CEN, ASTM, BISFA, IWTO, and DIN are listed with each of the test methods described below.

1.4. Climate

Fiber properties, especially those of natural fibers and of man-made fibers from natural polymers, depend on the testing climate. The relative

humidity is of primary importance here. In addition, fibers exhibit hysteresis when water is absorbed. Fibers take up different amounts of water, depending on whether they have been conditioned by adsorption or desorption. Therefore, fibers are tested in a standard climate:

Temperature $(20 \pm 2)\,°C$
Relative humidity $(65 \pm 2)\,\%$

Samples must always be conditioned to the standard climate in the adsorptive phase. When necessary, they must be dried first if, prior to testing, they have been exposed to a climate with more than 65 % R.H. Conditioning of samples is prescribed by standards ISO 139; ASTM D 1776; and DIN 53 802.

Currently, the European standardization commitees are striving for a change in the standard climate, with the aim of harmonization with testing laboratories in other fields such as plastics, paper, leather, and biology. The standard climate would then be:

Temperature $(23 \pm 2)\,°C$
Relative humidity $(50 \pm 5)\,\%$

1.5. Sampling

Fiber samples must be tested so that from the values obtained for a given property, the value of that property for the source material can be deduced. The sample must, therefore, be representative of the source material. Details of sampling are governed by the following standards and rules: ISO 1130; BISFA Rules; ASTM D 1060, D 1441, D 1771, D 2525, D 3333; DIN 53 803 (ASTM D 1771 has been discontinued without replacement, although copies are available from ASTM headquarters). A new standard is in preparation, prEN 12751:1997, which replaces all European national standards for sampling and later later the international standard ISO 1130.

2. Tests of Form and Mass

2.1. Length

Staple fiber length is an important fiber characteristic which greatly affects the spinning process as well as the quality of the textile end product. The lengths of natural fibers vary widely; therefore, many individual measurements are needed. The large number of fibers in a test lot and the inhomogeneities (e.g., from bale to bale or from batch to batch) also necessitate many individual measurements. Man-made fibers, with few exceptions, are cut to a certain length; substantially less variation occurs, but the length can be reduced by stresses on the fiber while it is being processed into yarn. This increases the deviation.

2.1.1. Single-Fiber Length

With the aid of two pairs of tweezers, a fiber is picked up at both ends, the crimp is pulled out by applying a slight tension, and the length is read off on a ruler. Crimp can also be removed by using a pair of tweezers to draw the fiber over a glass plate covered with paraffin oil or vaseline. The length is then measured with a ruler.

The measuring process can be simplified by mechanical devices. One of them is shown in Figure 1. With a pair of tweezers, the fiber is drawn under a loading weight and the crimp is thus removed. The results are presented in the form of a cumulative frequency diagram (Fig. 2); average fiber length and coefficient of variation are calculated.

Figure 1. Length measurement of single fibers
a) Loading weight; b) Velvet strips

Figure 2. Cumulative distribution of fiber length
L = average fiber length

Specific standards for length measurement are ISO 6989; ASTM D 3661; IWTO-5-60; DIN 53 808 T 1. For future reference, ASTM is developing another method (57-507) which is assigned "D".

2.1.2. Comb Sorter Method

A prepared fiber sample containing at least 10 000 fibers is first end-aligned with the aid of two banks of combs and special forceps (Fig. 3). The distance between pins depends on the type of fiber being tested: e.g., 3 mm for cotton, 10 mm for longer wool fibers. This distance is also the class interval for length classes. Once ordered, fibers of individual length classes are drawn from the bank and weighed. The weight is used to calculate the number of fibers of each class and, thus, to determine the average fiber length and the coefficient of variation. The result is presented as shown in Figure 2.

Mechanized devices that perform the ordering operation have been developed to test wool. Manual preparation, particularly end alignment, is difficult, time-consuming, and dependent on the care and skill of the tester. The procedure is applicable to fibers from flock (raw material), slivers, and rovings.

Standards for comb sorting are ISO 920; IWTO-1-66; ASTM D 519, D 1440, D 1575, D 3660; DIN 53 806.

2.1.3. Electronic Method – Capacitive Scanning

Two steps have been taken to simplify measurement of fiber length. (1) Parallelizing has been automated. This is more readily accomplished with sliver than with flock. Long fibers such as wool or long staple man-made fibers can be ordered more easily and accurately. (2) The

Figure 3. Comb sorting principle

frequency of individual length classes is determined by means other than drawing and weighing.

Figure 4. End-aligned beard with capacitive measuring principle
a) Clamp; b) Measuring condenser

WIRA Fiber Diagram Machine. The end-aligned beard is prepared by mechanical means. The ends are thermally bonded with plastic film. The fiber beard, which is now easy to handle, is drawn through the electrodes of a condenser, and the fiber mass for each length zone is measured. Standards are ISO 2646 and IWTO-16-67.

In the latest version of this machine, all characteristics of fiber length measurement, including the fiber length diagram, are printed out. The procedure is suitable for wool and long staple man-made fibers in sliver form.

Figure 5. Sketch showing principle of Almeter
a) End-aligned fiber sample; b) Measuring sled; c) Spindle; d) Measuring condenser; e) Detector; f) Stepping motor

Almeter. Fibers are end-aligned by a fully automatic sample preparation machine; the sample is then measured in the electric field of a condenser (Figs. 4 and 5).

This method is suitable for all fibers in flock or sliver form; the standards are ISO 2648 and IWTO-17-85.

2.1.4. Electronic Method – Optical Scanning

Optical Scanning of a Beard. The Fibrograph was developed specifically for measuring the length of cotton fibers. A beard is formed in a special comb by using the Fibrosampler. The beard is not end-aligned. In the measuring zone, the optical density of the beard is measured as a function of fiber length (Fig. 6).

Figure 6. Beard, not end-aligned, with optical scanning
a) Clamp; b) Optical sensor

Results are given in terms of so-called span length, defined as a function of cumulative frequency. The frequency diagram is called a fibrogram (Fig. 7). It has become customary to report the span length at 2.5 and 50 % frequency, abbreviated as the 2.5 % SL value and the 50 % SL value. In addition, the uniformity index is given, which correlates with the deviation of fiber length.

The Fibrograph was developed by SpinLab (Knoxville, USA) and is now available from Zellweger (Uster, Switzerland) under the trade name Uster Fibrograph 730. Many measurements can be made in a short time with this machine, which is especially important in testing raw cotton. Standards are ISO 4913; ASTM D 1447.

Figure 7. Fiber length measurement with Fibrograph Fibrogram shows 2.5 % and 50 % span lengths

Figure 8. Schematic of the AFIS system

Optical Scanning of Single Fibers. In the AFIS tester (AFIS = advanced fiber information system; Figure 8) flocks or slivers of fibers are individualized by a special device. The individual fibers are aligned longitudinally and stretched in an air stream. They then pass through a tapered channel into an optical measuring system. The data are evaluated by various modules, the most important of which is the L & D module, which measures fiber length and diameter (or width for nonround fibers). The fiber diameter or width is a measure of the fineness. Other modules measure fiber neps (Module N) and impurities (Module T).

2.2. Width, Thickness

Further geometric characterization of a fiber should include width or thickness and, for circular cross section, the diameter. Because of the multiplicity of fiber cross sections (see Section 2.4), a precise definition of one or more width measurements is not possible. Such measurements are, therefore, made only in exceptional cases. Fiber diameter is used as a characteristic of fineness only for wool (see Sections 2.3.2, 2.3.3, 2.3.4).

2.3. Fineness

Fiber fineness is defined as mass referred to a length (length-related mass). In the internationally accepted tex system (ISO 1144), the mass in grams is referred to 1 km:

1 tex = 1 g/km

From this, the decitex unit (dtex), frequently used for fibers, is derived:

1 dtex = 1 dg/km = 1 g/10 km

In certain countries, the millitex unit (mtex) is preferred:

1 mtex = 1 mg/km

2.3.1. Gravimetric Method

In gravimetric determination of fineness, the length and weight of the fibers are measured. The following practical method is used: a carefully parallelized, combed fiber bundle is cut at both ends when as much crimp as possible has been pulled out by suitable tensioning. The length should be as great as possible. Groups of 50 fibers – generally ten groups – are taken from this bundle. The total length is calculated from the cut length and the number of fibers. The mass of the individual groups of fibers is determined by weighing, and the fineness is calculated from the mass and the length. Standards are ISO 1973, EN 21 973; BISFA Rules; ASTM D 1577; DIN 53 812 T 1.

2.3.2. Projection Microscope Method (Fiber Diameter)

Because the fineness of individual wool fibers varies widely, the fineness distribution of individual fibers, in addition to the average fineness, must be determined. As a rule, at least 300 fibers must be measured. Figure 9 shows the results of a wool fineness measurement.

Figure 9. Example of wool fineness measurement
$\bar{x}$ = average fiber diameter

To calculate the fineness in decitex, the following formula is used:

$$T_d = \frac{\pi d^2 \cdot \varrho}{400}$$

where T_d = fineness, decitex; d = diameter, micrometers; ϱ = density, grams per cubic centimeter.

Appropriate standards are ISO 137; IWTO-8-89; ASTM D 2130; DIN 53 811.

2.3.3. Diameter Measurement with Laser Beam

Because measuring the fiber diameter of wool is very costly and time-consuming, simpler test methods are being sought. The Commonwealth Scientific and Industrial Research Organisation (CSIRO) of Ryde, New South Wales, Australia, has developed the so-called fiber distribution analyzer (FDA) [5]. Wool fibers are first cut to a length of ca. 2 mm and then finely dispersed in a nonswelling liquid. The liquid with the pieces of fiber then flows through a measuring chamber where it is measured by means of a laser beam and an electronic optical measuring device. About 30 – 50 fibers per second can be measured. The measurements are analyzed by computer, and the results are printed out.

This instrument is still used in many laboratories, but has since been replaced by a better and more effective measurement system (see Section 2.3.4) and is therefore no longer manufactured.

2.3.4. Projection Microscope Method with Image Analysis Techniques

With the aid of an electronic image analyzer, microscopic pictures of wool fibers can be suitably analyzed; thickness measurements can also be carried out. A more detailed description of this measuring procedure is contained in ASTM standard D 3510 (discontinued without replacement, copies are available from ASTM headquarters).

A new method for rapid and automatic measurement of fiber diameter has been developed by Australian Wool Testing Authority (AWTA) Ltd., Kensington, Victoria, Australia. It is based upon image analysis techniques and is called FIDAM (Fiber Image Display and Measurement). The measurement section consists essentially of a high-quality CCD (Capacitive Coupled Diode) television camera attached to a low-power microscope. The camera output feeds signals to a flash analog-to-digital converter (ADC) and then to a desktop personal computer which is the heart of the system. Sample preparation is also largely automatic; it involves microcoring the sample and spreading the resulting snippets, which are air-mounted, onto a large microscope slide. The calibration, which is linear, is based on the Interwoollabs' Calibration Tops and is very stable [6].

A further development is the OFDA (optical fiber diameter analyzer) instrument, marketed by Zellweger, Uster, Switzerland, in which computer image processing is performed through a projection microscope. In 50 s, 2000 – 5000 fiber sections can be measured (standard: IWTO-22-92).

2.3.5. Vibration Method

The vibroscope is based on the vibrating string principle. Linear density, or mass per unit length, can be calculated from the fundamental resonant frequency of transverse vibration of a fiber measured under known conditions of length and tension. This device is often combined with a fiber tensile tester. The measured fiber fineness is combined directly with the breaking force, and the breaking tenacity is calculated from it. The applicable standards are ISO 1973; EN 21 973; ASTM D 1577; DIN 53 812 T 2.

2.3.6. Airflow Method

The resistance of a plug of fibers to airflow depends on fiber fineness. For cotton, a characteristic called "Micronaire value" has been defined which can be read off the Micronaire instrument, designed for this purpose, as a function of resistance to airflow ("Micronaire reading"). The instrument is calibrated with fixed cotton standards. Resistance to airflow also depends on maturity. For wool, the scale is calibrated in micrometers. Figure 10 shows a sketch of the principle of this device. This instrument is now available from Zellweger (Uster, Switzerland) under the trade name Uster Micronaire 775.

Figure 10. Micronaire tester Sheffield 60 600
a) Pressure regulator; b) Scale; c) Rotameter plummet; d) Sample holder with fiber plug; e) Fiber compression plunger

Further details can be found in the following standards: ISO 1136, ISO 2403; ASTM D 1282, D 1448; IWTO-6-90, IWTO-28-89; DIN 53 941.

2.3.7. Microscopic Area Measurement

The area can be measured microscopically when few fibers are available for measurement and when these fibers are not circular in cross section. In this case, the above-mentioned methods cannot be used. Fiber cross sections for microscopic examination are prepared with a microtome, and drawings or photographs of these cross sections are made. The cross-sectional area can be determined by planimetry or by electronic analysis of the pictures; fineness is calculated from the area.

2.4. Microscopic Investigation of Cross Section

An investigation of fiber cross section may be necessary for several reasons:

1) Identification of fibers
2) Estimation of blend ratios
3) Determination of fineness (see Section 2.3.7)
4) Determination of maturity of cotton (Section 2.12)
5) Determination of depth of penetration of dyes or optical brighteners, sheath – core zones of fibers
6) Measurement of cross-sectional parameters, e.g., modification ratio (the "deviation" from a circle) and angle of lobes

Modification ratio is the ratio of the diameter of an inscribed circle, touching all the valleys in a lobed cross section, to the diameter of a circumscribed circle touching all the peaks in that cross section.

In addition, Special Instrument Laboratory (SpinLab) (Knoxville, TN 37901) has developed the "Fibrofine" Specific Surface Tester Model 820, used for measuring fiber fineness of cotton, to correlate with modification ratio measurements from cross-sections.

The *identification* of specific fiber types is possible by viewing their cross sections (Fig. 11). Man-made fibers, which are normally extruded from spinneret holes with circular cross section, can also be produced with cross sections

of different shapes (Fig. 12). Test Method 20 (AATCC) shows photographs of common textile fibers.

Figure 11. Cross sections of various fiber types
a) Cotton; b) Flax; c) Silk; d) Viscose rayon (normal); e) Most acrylic fibers (including modacrylic); f) Wool, cuprammonium rayon, polyester, polyamide, polypropylene, some acrylic fibers

Mixing Ratios. When the components of a fiber blend have different cross sections, an approximate blend ratio can be established through counting, by using photomicrographs of the cross sections. Mixtures of fiber of the same type but with different fiber fineness can also be examined in this way provided the difference in fineness is large enough (e.g., 3 – 6 dtex). Test Method 20 A (AATCC) "Fiber Analysis: Quantitative," has sections on microscopic analysis and procedures which cover this subject.

Dye Penetration. The distribution of dyes across the fiber cross section can be determined if the colorants are still recognizable in the relatively thin cross sections. The distribution of optical brighteners is determined easily under the microscope in UV light. Fibers with sheath – core structure can be made visible by using special dyes, e.g., Solophenyl Blue-Green BL (Ciba-Geigy). Some so-called bicomponent fibers can also be detected microscopically.

Figure 12. Some special cross sections in man-made fiber production

2.5. Microscopic Investigation of Fiber Surface

In certain cases, the fiber type can be identified by microscopic examination of a longitudinal view, i.e., of the fiber surface (Fig. 13). Thus, for example, wool can be recognized by its scale structure. When an unknown fiber must be identified, microscopic examination begins with the surface, because preparation of a specimen for longitudinal viewing is considerably faster and simpler than preparing one for cross-sectional viewing. Wool, cotton, flax, and viscose fibers can be identified unmistakably in this way. Test Method 20 (AATCC), also has information on longitudinal characteristics of natural fibers which is important to their identification.

Figure 13. Longitudinal view of some fiber types
a) Wool (characteristic: scales); b) Cotton (characteristic: longitudinal torsion); c) Flax (characteristic: lumen, transverse cracks); d) Viscose rayon (characteristic: longitudinal stripes)

For man-made fibers, the longitudinal view also indicates if the fiber contains delusterants or if it is of the bright type.

Microscopic examination of the longitudinal view can also serve many other purposes, such as

1) Determination of the surface structure of fibers, pores, vacuoles, cracks
2) Detection of foreign matter on the fiber
3) Inspection of crack formation at the fiber ends, an indication of overload
4) Investigation of thermal damage due to excessive friction
5) Checking wool fiber ends for hair roots, and differentiating between shorn wool and lime wool
6) Detection of insect damage

These investigations are best carried out with scanning electron microscopes (SEM) which provide high magnification and good depth of field.

2.6. Crimp

Crimp is very important for the processibility of fibers and the properties of textiles made from them. The crimp of wool is relatively uniform and characterized by true waves. Man-made fibers, on the other hand, may exhibit irregular crimp, and the shapes of the waves can differ widely (Fig. 14).

Figure 14. Different forms of crimped fibers
a) Wool; b) Synthetic fiber with stuffer box crimping

Several characteristics can be used to describe crimp; two of these are discussed in detail below.

2.6.1. Crimp Frequency

The number of crimp waves per centimeter is determined. The waves are counted either directly on the fiber or on enlargements, for example, with the aid of a projector. Care must be taken to count either the peaks or the valleys, not both (Fig. 15).

Figure 15. Definitions of crimping

In addition, the depth and width of the crimp waves can be measured with the aid of enlargements (ASTM D 2491; discontinued without replacement but available from headquarters).

2.6.2. Crimp Ratio, Crimp Retention

The crimp ratio E is defined by two parameters, the crimped length and the extended length of a fiber (Fig. 16).

Fibers should be straightened so that the crimp is removed but the material is not stretched. Crimp retention B is another characteristic that can be measured along with crimp.

The fiber which has been straightened to measure the crimp remains under this load for 5 min. After unloading, the fiber recovers partially; the extent depends on crimp retention. The length of this partially crimped fiber is then measured. The testing device used is the so-called crimp balance (Fa. Zweigle, Reutlingen, Federal Republic of Germany) which greatly facilitates the entire operation.

The change in length from the crimped to the straightened fiber can also be measured on a tensile testing machine. The Vibrotex machine (Lenzing AG, Lenzing, Austria) works by this principle.

Figure 16. Definition of crimp ratio and crimp retention
Crimp ratio:
$E = \frac{l - l'}{l}$
or $E\ (\text{in}\,\%) = \frac{l - l'}{l} \cdot 100\%$
Crimp retention:
$B\ (\text{in}\,\%) = \frac{l - l''}{l - l'} \cdot 100\%$

2.7. Density

2.7.1. Pycnometer Method

The pycnometer is a container of known volume, usually 50 cm^3. The mass P of the empty pycnometer is known. It is filled with a measuring liquid, preferably toluene, and weighed $(P + F_0)$. The container is then emptied, filled with the fiber whose mass is to be measured $(P + G)$, and filled to the mark with measuring liquid $(P + G + F)$. From these four weight determinations and the known density of the measuring liquid, the density of the fiber can be calculated.

2.7.2. Density Balance (Archimedes' Principle)

A small specimen is weighed in air and then immersed in a liquid of lower density than the fiber. The difference in weight is equal to the weight of the liquid displaced, i.e., the volume of the fiber specimen times the density of the fiber specimen times the density of the liquid.

Displacement liquids used are *n*-heptane ($\varrho = 0.648$ g/cm^3) or methanol ($\varrho = 0.791$ g/cm^3). The standard applied is ASTM D 276.

2.7.3. Gradient Method

A liquid column with a density gradient is prepared by stacking layers of two liquids of different densities (e.g., xylene with $\varrho = 0.9$ g/cm^3 and pentachloroethane with $\varrho = 1.7$ g/cm^3), one above the other. The fiber sample to be measured remains suspended at the height at which the densities of liquid and fiber coincide.

2.8. Chemical Identification of Fibers by Solubility

Specific fiber types are also identified by a combination of microscopic and solubility tests. To save space, a complete solubility test scheme is not presented here (see ASTM 276). Some solvents for fibers are

Wool: potassium hydroxide
Polyamide: hydrochloric acid (6 mol/L)
Polyacrylonitrile: dimethylformamide
Polyester: 1,2-dichlorobenzene
Cellulose acetate: acetone

2.9. Other Identification Methods for Fibers

Other characteristics can be used to identify fibers, provided suitable measuring devices are available:

Fiber density (see Section 2.7)

Melting point (see Section 5.1)
Infrared spectroscopy
Refractive index and birefringence

The methods, including all necessary specifications and characteristic IR spectra, are described in ASTM D 276.

2.10. Identification of Wool and Hair

The wool and hair of different animals consist of the same basic substance; to differentiate among them under a standard microscope is often difficult or impossible. Other characteristics, such as fineness, fiber length, and crimp, are not sufficiently different to assure unambiguous identification. The scanning electron microscope has proved suitable for identifying various wools and hairs. Good information is available in Test Method 20 of AATCC.

Distinguishing characteristics are the scales of the fibers and their thickness. Institutes that have a scanning electron microscope and a staff experienced with animal fibers are capable of carrying out such investigations [7], [8].

2.11. Analysis of Fiber Impurities and Extractable Matter

Natural fibers contain various impurities. In cotton, these impurities originate predominantly from the cotton plant. During ginning, cotton fiber is contaminated further with seed-coat fragments. Scoured wool also contains vegetable impurities which cannot be removed by scouring. In addition, the surface is covered with wax, grease, or oil, either of natural origin or applied subsequently. Those substances which are applied later are called preparations or finish agents and, collectively, extractable matter (i.e., substances that can be removed by organic solvents).

2.11.1. Trash and Dust Content of Cotton (Nonlint Content)

Raw cotton contains various impurities such as stems, leaves, sand, seed-coat fragments, and dust which, collectively, are called trash and dust. Slivers from carding and drawing may also be more or less contaminated, depending on the intensity of cleaning. The various testing machines for determining trash and dust operate on the mechanical – pneumatic principle. Two of these are mentioned below.

Shirley Analyzer. A known weight of raw cotton, partially processed cotton, or waste is fed into the machine. The machine separates the foreign matter from the cotton and discharges the non-lint cotton into a separate chamber. The amounts of lint and nonlint recovered are calculated as a percentage of the original specimen mass (ASTM D 2812).

Micro Dust and Trash Tester. The Institute of Textile Technology and Process Engineering Denkendorf (Germany) has developed a testing machine based on the opening device of a rotor spinning machine, which separates trash and dust from the fiber material. Trash and micro dust are picked up separately by separation and suction, respectively, and weighed [9]. This instrument has been adopted by Zellweger (Uster, Switzerland), modified, and sold under the trade name MDTA 3 (micro dust and trash analyzer).

2.11.2. Honeydew on Cotton

The secretion of the white fly, a sticky sugar-containing substance called honeydew, is deposited on the cotton shrub. Honeydew is very disruptive during spinning. Various procedures have been developed in recent years for determining honeydew, none of which are satisfactory. The highly nonuniform distribution of honeydew deposit creates difficulties. Some procedures utilize chemical test solutions which discolor appropriately in the presence of sugar [10–12], e.g.,

Benedict test
Perkins test
Bremer honeydew test

By means of extensive tests, the "Honeydew Working Group" of the International Cotton Test Conference has found that these tests are not fully applicable to industrial conditions. Various measurement techniques in which the stickiness of fiber mats between heated metal plates is used

as a measure of the honeydew content are being evaluated, and corresponding standards are in preparation.

2.11.3. Grease Content of Wool – Extractable Matter Content

Various solvents can be used to dissolve grease or oil. Because other substances can be picked up at the same time, depending on the solvent, the term "extractable matter" is more accurate.

The following solvents are used for wool:

Ethanol ASTM D 584
Trichlorotrifluoroethane ASTM D 1574
Dichloromethane ISO 3074; IWTO-10-62

Fiber samples are treated with the appropriate solvent in a Soxhlet extractor. The amount of material extracted is referred to the dry or commercial weight of the wool.

2.11.4. Preparation and Finishing Agents for Man-Made Fiber

A Soxhlet extractor is also used for man-made fibers; however, a different solvent is employed. No uniform international standard exists. The following solvents are specified in DIN 54 278:

Methanol: polyester, polyacrylonitrile, and poly(vinyl chloride) fibers
Petroleum ether: polyamide and cellulose acetate fibers

Another reference is ASTM D 2257, Standard Test Method for "Extractable Matter in Yarns," which can be applied to staple fiber. It uses Soxhlet extractions with trichlorotrifluoroethane and then ethanol.

2.12. Maturity of Cotton

Cotton contains both fully matured and immature fibers. The characteristic of immature cotton fibers is a wall width less than the lumen width (Fig. 17). The degree of maturity can be determined by various procedures.

Figure 17. Mature and immature cotton fibers
a) Before husk is opened; b) After husk is opened

Microscope. Fibers are swollen by addition of an 18 % solution of sodium hydroxide. Because of their smaller width, immature fibers can be spotted and counted under a microscope. In polarized light, immature fibers can be recognized even without swelling; the same is true for the microscopic examination of fiber cross sections. Standards are ISO 4912; ASTM D 1442; DIN 53 943 T 2 and T 3.

Fiber Fineness. Fineness involves a determination of the maturity index and is used to estimate the linear density of loose cotton fibers by measuring, with an airflow instrument, the resistance of a plug of cotton fibers to airflow before and after treatment with a sodium hydroxide solution (Causticaire method). The standards are ASTM D 2480; DIN 54 943 T 4.

A new procedure measures the linear density, by using an airflow instrument, at two different compression ratios of the cotton plug. The two readings are substituted in a formula, and the degree of maturity is calculated. The standards are ISO 10 306, EN 30 306, ASTM D 3818.

Dyeing. Immature fibers acquire very different coloration, especially with certain test dyes. The red – green test is based on this property (red coloration = mature; green = immature). The degree of maturity is estimated from a comparison with standard samples.

Fibrograph. Another method for measuring cotton maturity is ASTM D 3817, Standard Test Method for "Maturity Index of Cotton Fibers by Fibrograph" which uses the Uster Fibrograph 730 (see page 6).

3. Tensile Properties

3.1. Tensile Test

To determine its deformation properties, a fiber is clamped at each end in the jaws of a tensile testing machine and loaded in the longitudinal direction until it breaks. According to standards in 1989, only tensile testing machines that operate by constant rate of extension principles may be used. The relevant terms are defined as follows:

Gauge Length. The gauge length is the distance between the clamp jaws as traversed by the mounted specimen (which is not always a straight line between the jaws, as is the case with capstan clamps). The gauge length should not be less than 10 mm; 20 mm or more is preferred. The method ASTM D 2101, which is applied on filaments, uses a 25-mm gauge length.

Breaking Load. The maximum force applied to a specimen in a tension test is called breaking load. The force is expressed in newtons, centinewtons, or millinewtons. In ASTM standards, it is also expressed in gram-force (gf).

Tenacity. The tensile stress expressed as force per unit linear density of the unstrained specimen is called tenacity. Tenacity is expressed in centinewtons or millinewtons per tex; ASTM also uses gram-force per tex (gf/tex). The tenacity corresponding to the breaking load is called *breaking tenacity.*

Elongation. Elongation is the increase in length, expressed in units of length or as a percentage of the gauge length (Fig. 18). The elongation corresponding to the maximum load is called *elongation at break.*

Figure 18. Load – elongation curve

Tensile testing machines must have the precision necessary to measure fibers with sufficient accuracy at a gauge length of 10 mm and at relatively low tensile forces. The rates of elongation are determined as a function of the expected elongation (Table 1). In addition to the numerical indication of force and elongation, the testing machine must be equipped with a device on which the load – elongation curve can be recorded. Elongation rate (percent of initial specimen length in mm) at the corresponding elongation at break

Most testing machines on the market today are combined with equipment for measuring fineness. Fineness is first measured by the vibroscope method on each individual fiber, and the result is fed into a computer. The same fiber is then clamped in the tensile testing machine and tested. The measured force is also fed into the computer, which then calculates the tenacity at break. In addition, the computer calculates an average of all the individual values and all other statistical parameters; as a rule, at least 50 individual values are required per test.

For wet testing, which is common for viscose fiber, for example, the tensile testing machine must be equipped with a suitable moistening device. The fiber clamped in the jaws is wetted directly.

Standards are ISO 5079; EN 25 079; BISFA Rules; ASTM D 3822. The method ASTM D 2101 is used for longer fibers (25-mm gauge length).

Figure 19. Determination of elastic properties of fibers
A to B: load to required elongation
B to G: wait (simultaneous relaxing of stress)
G to C to A: back to zero elongation; wait
A to D to H: load to same elongation
Permanent deformation, % $\frac{\overline{AD}}{\overline{AE}} \cdot 100$
Tensile strain recovery, % $\frac{\overline{DE}}{\overline{AE}} \cdot 100$

Table 1. Elongation rate (percent of initial specimen length in mm) at the corresponding elongation at break

Estimated elongation at break, %	Elongation rate (ISO, EN)	Estimated elongation at break, %	Elongation rate (ASTM)
< 8	50	< 8	10
≥ 8	100	8 – 100	60
		> 100	240

Figure 20. Determination of modulus
A) Initial modulus; B) Secant modulus; C) Tangent modulus
$\left(\frac{\overline{PB}}{\overline{AB}/l_0}\right)$
where l_0 = specimen length (gauge length)

3.2. Elastic Behavior

The elastic properties of fibers are measured by determining the amount of recoverable energy exhibited by a fiber when it is stretched to a predetermined extension at a specific elongation rate, held at this extension for a specified length of time, and finally relaxed at the same rate at which it was extended. The fiber can also be loaded in multiple cycles, and the loading and unloading time in each can be varied.

Permanent deformation and tensile strain recovery can be determined from the load – elongation curves (Fig. 19). These values can be ascertained at various degrees of elongation, e.g., 2, 5, and 10 %. Standards are ASTM D 1774; DIN 53 835.

3.3. Modulus

The modulus is the ratio of the change in tenacity, expressed in centinewtons per tex, to the change in elongation, expressed as a fraction of the original length. These values can be obtained in various ways from the tenacity – elongation curve (Fig. 20). The standard used is ASTM D 3822; ASTM D 2101 is used for longer fibers (25-mm gauge length).

3.4. Loop Tensile Test

Loop breaking tenacity is a fundamental property used to establish limitations on fiber processing and on end use. The specimen, consisting of two single fibers looped in a configuration shown in Figure 21, is broken on a testing machine with a constant rate of extension.

Figure 21. Loop specimen configuration

3.5. Bundle Stress Test

Tensile testing of single fibers is very time-consuming and requires careful handling. The relatively short fiber length of cotton presents additional problems. For this and other reasons, collective test methods have been developed in which a bundle of parallelized fibers is mounted

in suitable clamps and broken. For some machines, zero gauge length is recommended; for others, the gauge length is 3.2 mm (1/8 inch).

Pressley Tester. For the Pressley tester, the standard gauge length is zero, but it can be adjusted to 3.2 mm. A combed, parallelized bundle of cotton is secured in two special clamps and loaded by releasing a weight that slides down an inclined track. When the bundle breaks, the weight stops on the track and the breaking force can be read off the scale. The fiber bundle remaining in the clamps is then weighed so that the breaking force can be related to fineness. The machine is calibrated with standard cotton (test cotton), prescribed by the U.S. Department of Agriculture (USDA). The result is calculated as the Pressley Index (DIN) or as breaking tenacity in gram-force per tex (ASTM). Standards are ISO 300; ASTM D 1445; DIN 53 942.

Stelometer. In a stelometer, force is applied by the pendulum principle. The gauge length is 3.2 mm. In addition to the breaking force, the elongation at break can also be read. By means of fineness (weight and length) of the fiber bundle, tenacity at break is calculated in units of centinewtons per tex and, in the United States, also in gram-force per tex. This instrument is available under the trade name Uster Stelometer 654.

Figure 22. Moisture uptake of different fibers at 25 °C [1]

Test cotton or, if wool is to be tested, test wool can be used for calibration. Both are prescribed by the USDA. Standards are ISO 3060; IWTO-32-82; ASTM D 1445, D 2524. In principle, any tensile testing machine with suitable force range can be used to perform the bundle test, provided appropriate clamps are available (ASTM D 1294).

4. Behavior toward Water

4.1. Moisture Adsorption

Fibers take up more or less water from the atmosphere, depending on hygroscopicity and relative humidity (Fig. 22).

Moisture uptake is subject to hysteresis (see Section 1.4); i.e., fibers take up different amounts of moisture, depending on whether they are brought into the standard climate from the dry or from the wet state. Moisture affects various physical properties and is important in calculating commercial weight.

4.1.1. Oven Drying Test

The fibers are weighed, dried in an oven with hot air (105 °C), and reweighed. The difference between the original mass and the oven-dry mass is the moisture content, expressed in percent. Standards are ISO 6741; IWTO-33-88, IWTO-34-85; BISFA Rules; ASTM D 629, D 1576, D 2495, D 2654; DIN 53 800. For calculating commercial weight, various organizations specify commercial moisture regain, but no uniform international standard existed in 1989 (see also BISFA Rules; ASTM D 1909; DIN 54 201).

4.1.2. Other Tests for Moisture Content of Fibers

Fiber moisture also affects its electrical properties, e.g., electrical resistance or capacitive parameters in a condenser field. On this basis, instruments have been developed with which the moisture content of fibers can be measured. They are usually not accurate enough to determine commercial weights, but because they can be read directly and are easy to use, they have been adopted for control purposes.

Measurement of Electrical Resistance. Two needle-shaped electrodes are inserted in the fiber material (e.g., in the bale) and moisture is measured via resistance.

Capacitive Measurement. Fibers, even whole bales, are measured in the electrical field of a condenser. These instruments must be calibrated by oven drying. This calibration should be carried out at two different moisture levels for each fiber type.

4.2. Water Absorption

Water is taken up from the liquid phase in different ways. Part of the water enters the interior of the fiber, part of it is bound to the fiber surface, and part remains between fibers as a result of capillary action. The last is especially difficult to measure because it is greatly affected by the position of the fibers and the packing density. Therefore, water retention is used as a measure of water absorption because the conditions of measurement are defined more precisely and are easier to observe.

Determination of Water Retention. A fiber specimen is placed in a basket, immersed in water, and subsequently centrifuged. The conditions for centrifuging are defined by the standards

ASTM D 2402: 1 h at an acceleration of 1000 g (9800 m/s^2)
DIN 53 814: 20 min at an acceleration of 800 – 1000 g (7800 – 9800 m/s^2)

In this method, water retained by fiber masses includes (1) water absorbed from the prevailing atmosphere, (2) water imbibed after immersion, and (3) moisture adhering to fiber surfaces after being subjected to acceleration.

5. Thermal Behavior

Changes produced by thermal effects are almost exclusively determined on the yarns or textile fabrics made from fibers rather than on the fibers themselves. Only a few characteristic temperatures can be measured on the fibers and be used to identify fiber types:

Glass transition temperature
Softening range
Melting point
Decomposition temperature
Autoignition point
Char temperature

Two determinations used more frequently with fibers – melting point and burning test – are discussed below.

5.1. Melting Point

The melting point can be determined for fibers by means of a microscope equipped with a special heating device. This is a way of distinguishing nylon 6 from nylon 66, for example (standard ASTM D 276).

5.2. Burning Test

The burning test serves exclusively to identify fibers. Flammability, combustion behavior, odor, and residue are characteristic of individual fiber types (see also Test Method 20 of AATCC). Some examples are

Cellulose Fibers (cotton, viscose rayon)	easily flammable; burns rapidly with bright flame; white-gray ash
Wool	difficultly flammable; odor of burnt hair; coal-like ash
Polyamide	moderately flammable; melts while burning, drips; sphere-like residue

6. Dyeing Properties

6.1. Laboratory Dyeing

Dyeing tests are carried out preponderantly on textile fabrics and yarns. If these are not available, test dyeings are carried out on fiber flock in laboratory dyeing apparatus. In flock dye houses, such test dyeings serve as control samples. The test dyeing itself can take place in simple dye beakers or in a dyeing apparatus with stirrers and programmed heating cycles. For high-temperature dyeing (above the boiling point), a special apparatus is required.

6.2. Identification of Fiber Type by Dyeing (Neocarmine)

Neocarmine dyes (e.g., Neocarmine W [*51394-11-7*], obtainable from FESAGO, Heidelberg, Federal Republic of Germany) are used to identify fiber types by comparison with a color scale. This is an especially useful method if a microscope or other expensive equipment is not available.

7. Processing

7.1. General

The processibility of fibers into yarns or nonwovens is important to spinners and nonwoven producers. This property is highly complex and contains many subproperties and characteristics which make laboratory testing difficult. Starting with a processing test on production machinery, a scaled-down, semiworks machine is constructed in which the number of production units (e.g., the number of spindles on a spinning machine) is reduced. The amount of fiber to be processed is thus kept to a minimum, but a certain amount of information on processibility is lost.

Occasionally, attempts are made to predict processibility with the aid of specially developed testing devices. This is only partially successful. With the present state of the art, only a few processibility characteristics can be estimated from such devices and from spinning tests on semiworks spinning units.

7.2. Spinning Devices for Trials

A mini carding machine is used to open the fibers. Next, the fiber web is parallelized on small draw rolls and spun on a spinning tester. The spun yarn can be checked for various properties. Rovings can also be fed to spinning positions to determine the behavior of fibers in the spinning process or to investigate certain spinning parameters.

Only limited conclusions concerning processibility on production machines can be drawn from such tests, especially if high-production machines are involved. For this reason, a test run under actual operating conditions on the production machine itself is often preferred.

7.3. Electrostatic Charging

Fibers that absorb little moisture, which include all synthetic fibers, tend to be electrostatically charged. They are, therefore, provided with antistatic finishing agents. The antistatic effect depends on the relative humidity of the atmosphere.

The tendency to be charged electrostatically can be measured with the aid of so-called field-intensity meters at the card or mini card or on the drawing frame. The measured field intensity in volts per meter, together with the relative humidity, indicates the running properties that can be expected and possible processing problems.

Figure 23. Principle of rotor ring method
a) Feeding of fibers; b) Feeder; c) Opener; d) Rotor ring (fleece of parallelized fibers); e) Rotor; f) Feeding tube

7.4. Rotor Ring Method

The rotor ring device developed at the Institute for Textile Technology and Process Engineering Denkendorf (Rotor Ring Device 580) consists, in essence, of a rotor spinning unit. By measuring the width of the fiber ring taken from the rotor and the electrical output of the opening roll, important conclusions can be drawn concerning the processibility of fibers, crimp, finish

properties, fiber – fiber friction, and fiber – metal friction (Fig. 23) [13].

7.5. Combination of Micro Dust and Trash Analyzer with the Rotor Ring Method and a Spinning Device for Trials

At the Institute for Textile Technology and Process Engineering Denkendorf, a combination of the following test methods has been developed and is marketed by Zellweger under the trade name Uster Quickspin System:

- Micro Dust and Trash Analyzer, MDTA 3
- Rotor Ring Method, Rotorring 3 (see Section 7.4) with a large rotor (diameter ca. 320 mm)
- Quickspin rotor spinning device for procucing a rotor yarn

A modified rotor ring device (see Fig. 23) separates micro dust and trash by filtration and suction and weighs them. The cleaned fibers pass through the feeding tube (f) into the rotor (e), whose diameter of ca. 320 mm is such that the fiber ring removed from the rotor has a length of ca. 1 m. The fiber ring is used for the determination of some of the properties described in Section 7.4. The fiber ring is then cut to give a ca. 1 m long sliver, which is spun into a yarn ca. 200 m in length. Physical investigations on the yarn then allow conclusions to be made about the properties of the fibers.

The Quickspin System is mainly intended for rapid evaluation of raw cotton. It enables cotton dealers and processors to quickly evaluate the quality of a cotton delivery on the basis of small samples.

8. Automated Test Units

Test lines have been developed for testing cotton where several fiber properties can be determined sequentially, largely in an automated or mechanized mode. Control of the operation, calibration, recording, and analysis of results are performed with the aid of computers. The essential properties measured are

- Fiber length (fibrograph principle)
- Fiber strength and elongation (bundle test)
- Fineness (Micronaire)
- Trash content (scanning)
- Color

Other combinations, including measurement of maturity or trash and dust content, are possible. Two manufacturers have produced such units, several hundred of which are in use worldwide:

1) High Volume Testing (HVT) from Spinlab, Inc., Knoxville, Tennessee, and
2) High Volume Instruments (HVI) from Motion Control, Inc., Dallas, Texas

The units are calibrated with test cotton whose properties are determined and approved by a central test laboratory. This can be considered something of a disadvantage. Calibration by means of a standard independent of the material to be tested would be preferable. The advantage of these test lines is that complete measurement of several properties can be performed in a very short time (a few minutes) by one person. With a complete knowledge of raw materials data, directed use in spinning becomes possible.

1. Introduction

The term *film* is applied to thin materials present in a continuous planar form, which are at the same time self-supporting and flexible. A film may consist of one or more layers, usually of differing composition. The term generally encompasses both metallic and polymeric substances, which may be either homogeneous or made heterogeneous by the presence of incompatible additives or blending components. In this article, a film is assumed to be a polymeric material which can be wound into a roll. Film thicknesses range from 0.5 µm to ca. 1 mm.

The characteristics of a film are determined primarily by the raw materials employed, but they are additionally affected by processing methods, modification, and converting (e.g., stretching, coating and lamination).

Film materials are of considerable economic importance. In 1986, the annual worldwide consumption of film for packaging and technical applications was ca. 11×10^6 t. Figures for the worldwide consumption of the more important film materials are listed in Table 1.

Films are used as flexible packaging materials, as insulation for electrical conductors, as protective layers on sensitive surfaces, and as windable base materials for subsequent application of magnetic coatings, electrically conducting, and light-sensitive layers as well as printing inks. Multitudes of film and sheet types have been developed to meet the increasing demands of these applications. These products provide a broad spectrum of mechanical, optical, and electrical properties, as well as various degrees of permeability and stability to temperature and aggressive media.

Table 1. Worldwide consumption of some of the most important types of film in 1986*

Material	Consumption, 10^6 t
Low-density polyethylene (LDPE)	8.00
Polypropylene, biaxially oriented (BOPP)	0.55
Poly(vinyl chloride) (PVC), rigid and plasticized	1.42
Poly(ethylene terephthalate) (PETP), biaxially oriented	0.55
Cellophane	0.26

* Hoechst marketing research, Kalle Works, Federal Republic of Germany.

Historical Aspects [1]. Polymeric films were first developed at the end of the 19th century, when cellulose nitrate was introduced as a base material for photographic emulsions. Other cellulose-based films followed, the most important of which were derived from cellulose acetate and cellulose hydrate. Cellulose triacetate films quickly replaced the highly flammable cellulose nitrate films in the photographic industry; cellulose hydrate films (cellophanes) became important packaging materials, maintaining their dominance until polyolefin films were introduced in the 1950s. Cellophane coated with cellulose nitrate or poly(vinylidene chloride) also played a key role in this respect due to its low permeability to water vapor and oxygen, coupled with desirable sealing properties.

All cellulose-based films are prepared from polymer solutions, however the subsequent introduction of totally synthetic polymers has led to new film production methods, as well as new types of films with unique properties. These developments have been encouraged by the close working relationship between fiber and film producers, particularly in terms of polymer compositions and processing technology.

Important milestones in the development of films included the introduction of

1) poly(vinyl chloride) films in the late 1930s
2) low-density polyethylene films in the late 1940s
3) biaxially oriented polyester and polypropylene films in the 1950s

Parallel and subsequent to these developments, a series of specialty films has emerged. These films are distinguished either by high mechanical or thermal stability, or by special properties such as impermeability to oxygen, advantageous electrical characteristics, or resistance to chemical attack.

2. Production Technology [2]

Generally speaking, the manufacture of films from both natural and synthetic polymers relies on two basic techniques:

1) solution casting
2) thermoplastic film forming

The method chosen is generally determined by the behavior of the starting materials with respect to solvents and temperature. However, in certain cases the desired product characteristics are decisive.

For *solution casting,* the raw materials must first be dissolved in an appropriate solvent. The solution is then pressed through a slot die either onto a moving belt or into a precipitation bath.

*Thermoplastic film forming*can be divided into two categories: (1) calendering (film formation in a rolling process) and (2) film formation from a melt (an extrusion process).

2.1. Solution Casting

Solution casting is applicable to soluble polymers that are difficult or impossible to thermoform. It also has advantages in the preparation of films for optical applications. Cellulose acetate, polycarbonate, and polyimide films are prepared in this way.

Solution casting consists of three stages:

1) preparation of the casting solution
2) film formation on a moving surface (drum or endless belt) or in a precipitation bath
3) removal of residual solvent

Figure 1 is a schematic illustration of a belt casting machine that is suitable for the production of cellulose acetate film.

The casting solution is prepared in a large agitator vessel, if possible using a low-boiling solvent. The solution is normally very viscous (ca. 20 Pa · s) and is passed through a filter press equipped with a cotton filter. After the viscosity has been checked, the solution finally enters the casting reservoir. Entrapped air is removed either by evacuation or by heating.

The solution is fed from the reservoir under pressure through the die and is cast onto a rotating drum or a moving metal belt. The die gap is adjusted according to the desired thickness of the film.

The metal belt may be made of copper, nickel, or steel, and its surface finish is of critical importance in determining the characteristics of the resulting film. For optical-grade films, the surface must be polished and filtration must be highly effective. Belt dimensions range from 25 to 55 m in length and 1 to 2 m in width; belt speed varies from 1 to 60 m/min, depending on the desired thickness of the film.

The film is dried on the belt by a countercurrent of warm air and is then removed, further dried, and wound. Typical thicknesses of films prepared in this way are 15 – 250 µm.

In some cases, the polymer solution emerges from a slot die directly into a liquid precipitation bath. The polymer solvent is miscible with the bath fluid, whereas the polymer is insoluble in this fluid. Consequently, the polymer coagulates in the bath to form a gel film with a microporous structure. Thus, this process is frequently employed for the preparation of membranes (→ Membranes and Membrane Separations).

Cellulose hydrate (cellophane) films [3] are produced by a modification of this process in which the gel film undergoes a chemical reaction. The casting solution is prepared by reacting cellulose with caustic soda solution and carbon disulfide to form viscose. The resulting xanthate solution is then pressed into a spinning bath containing sulfuric acid, causing decomposition of the xanthate and forming a gel web composed of regenerated cellulose (see also → Cellulose, Chap. 3.1.).

A slot die is immersed in the precipitation bath (see Fig. 2). Shortly after its formation, the gel film possesses sufficient stability to permit its transport over rollers. The film is subsequently washed and bleached, passed through plasticizer baths, dried, and wound.

Film thickness ranges from 12 to 45 µm with a typical width of ca. 2 m. Production rates of 80 m/min are common for films in the mid-thickness range. The normal slot die may be replaced by an annular orifice, in which case the product is a tube of regenerated cellulose [4]. Further processing is as described above for flat cellulose hydrate films.

2.2. Thermoplastic Film Forming

2.2.1. Calendering [5–7]

Only polymers with a broad range of plasticity and high viscosity can be processed by the calendering method; these criteria are met by homo- and copolymers of poly(vinyl chloride) (PVC).

The production of calendered (e.g., PVC) film is shown in Figure 3; three steps are involved:

1) preparation of a blend of the components in a mixer
2) homogenization and plastification
3) film formation in the calender

The powdered mixture is usually converted into a fused mass by continuous compounding in a kneader or planetary-gear extruder using heat, shearing forces, and pressure. The mass is then rolled into a film web, ideally with a four- or five-roll calender, in which the nip rolls are mounted in an "L"-form. These rolls are made of steel or cast iron and they generally have a smooth surface. The nip rolls are heated to 180 – 220 °C, depending on the process and the polymer mixture; heating must be uniform. The calendered

Figure 3. Film production by calendering
a) Mixer; b) Kneader; c) Feed band; d) Calender; e) Cooling and tempering rolls; f) Winder

web then passes over cooling rolls followed by an edge-trimmer, in some cases a stretching facility, and finally a winding unit. Calendering equipment operates at high pressure and must, therefore, be solidly constructed, making it very expensive. The largest production facilities for processing plasticized PVC have nip rolls 85 cm in diameter and are 280 cm wide. Calenders for rigid PVC utilize rolls up to 70 cm in diameter and are 250 cm wide. Production rates of 50 – 100 m/min are achieved depending on the desired film thickness; with stretching, line speeds approach 300 m/min. These figures correspond to an output of 500 – 2000 kg/h.

2.2.2. Extrusion [8]

Advantages of extrusion include a wide range of attainable film thickness, large-scale processing, and the fact that recovery systems for expensive solvents are not needed.

The technique utilizes an extruder to melt the polymer, a die to confer shape to the melt, and a cooling system to solidify it. The process is applicable only to raw materials for which there is a sufficiently large temperature difference between melting and the onset of decomposition (e.g., polyolefins, polyamides, and polyesters).

Chill Roll Extrusion . Figure 4 is a schematic illustration of a chill roll extrusion line. Moisture-containing raw materials (moisture content usually $\ll 1\,\%$) are subjected to continuous or discontinuous drying, preferably utilizing heated air or a vacuum, prior to melting in the extruder.

Various extruder designs can be used including single-screw and twin-screw extruders, the latter with either corotating or contrarotating screws. Extremely high outputs of 4 – 5 t/h can be achieved with two extruders combined in sequence (tandem extruder). Single-screw extruders are the most common. Screw geometry must be adapted to the raw materials being processed and has a major effect on the output and quality of the melt. The largest single-screw extruders currently in use have a screw diameter (D) of 30 cm and a screw length of 30 D.

The melt is filtered in one of several ways depending on the desired purity: wire mesh, sintered metal, and wire–felt disks are all used. The filtered raw materials are forced through a slot die. The required pressure can normally be achieved with the extruder, however in special cases a gear pump is installed before the filter to ensure constant metering of the melt. In coextrusion (see Section 2.4.2), the die combines several different melt streams. The width of the die and the die gap determine the width and thickness of the film, respectively. In large production units, the dies may be as wide as 3.5 m. Adjustment of the die gap permits the film thickness profile to be corrected during production. Initial adjustment and readjustment can be performed either manually or automatically, e.g., by thermal expansion of adjusting screws that are heated as a function of the relative film thickness.

When the melt film emerges from the die, it is cast onto a highly polished, chrome-plated chill roll. The takeoff speed depends on both film thickness and output and may be as high as

Figure 4. Film production by chill roll extrusion
a) Extruder; b) Filter; c) Slot die; d) Air knife; e) Cooling roll; f) Device for measuring film thickness; g) Tension rolls; h) Corona treatment; i) Edge trimming; j) Winding

100 m/min. Entrapment of air between the melt and the roller surface is prevented by using an air jet (air knife), electrostatic "pinning", or a vacuum device.

The thickness of the film is measured with the aid of a traversing radiation source and detector. The film is then edge-trimmed and wound to a roll. If the film is to be printed, corona pretreatment can also be carried out (see Section 2.4.1).

The film is usually cut to the designated width in a separate process–the actual width depending on the application. If monoaxial or biaxial orientation is desired, the film is fed directly into a stretching unit (see Section 2.3) without intermediate winding.

Film Blowing (Blown-Bubble Extrusion). In the film blowing process, the filtered melt is pressed through an annular die instead of a slot die; this results in the production of a tubular film (Fig. 5). The tube (or "bubble") is inflated by means of air blown through the center of the die. The film is thereby expanded at a temperature close to its melting point and is then cooled by an airstream located above the die. A number of techniques are employed for air cooling; the most common involves passing the tube through a cooling ring. Supplementary internal cooling is also usually used if a high throughput is required. If biaxial stretching is to be performed, the melt must be solidified immediately after it emerges from the die (see Section 2.3.2).

The cooled tube is collapsed by transporting it through a convergent collapsing frame and a set of nip rolls. The film can then either be wound directly as a flattened tube or slit open on both sides and directed to two separate winding stations. The largest film blowing systems utilize annular dies with a diameter of 2 m and an output of 1.5 t/h.

The film blowing process is employed mainly for polyolefin and polyamide films. Multilayer films can be produced by coextrusion of tubular films (see Section 2.4.2).

2.3. Stretching [8]

Many films acquire their desired properties only after stretching. Stretching below the softening temperature orients the polymer molecules and crystallites in the direction of stretch, leading to changes in the stress–strain characteristics of the material. Both the modulus of elasticity and the ultimate strength are increased by this process, but elongation at break and dimensional stability with respect to temperature decrease. A number of other characteristics may be altered as well, depending on the type of film involved, e.g. gas permeability, electrical properties, heat sealability, abrasion resistance, coefficient of friction, puncture resistance, density, and optical properties. Stretching can be conducted either solely in the machine (longitudinal) direction (monoaxial

Figure 5. Film production by the blowing method

stretching) or in both the machine and the transverse directions (biaxial stretching).

Monoaxial stretching (see Section 2.3.1), which is also commonly used in the production of high-strength fibers, produces films of enhanced strength in the direction of manufacture. The resulting films are thus anisotropic.

Biaxial stretching (see Section 2.3.2) can be conducted in one or two steps (simultaneous and sequential stretching, respectively). Sequential stretching may result in either anisotropic or isotropic films depending on the ratio of the final length to the initial length (the draw ratio). Simultaneous stretching tends to produce isotropic films.

The majority of films prepared from orientable polymers are amenable to either sequential or simultaneous biaxial stretching. However, films derived from polymers with a high rate of crystallization during orientation (stress crystallization) [e.g., some polyamides, poly(butylene terephthalate), and ethylene–tetrafluoroethylene copolymer] can only be oriented by simultaneous stretching.

2.3.1. Monoaxial Stretching

Monoaxial stretching is accomplished by subjecting a film to an increasing velocity gradient as it passes through one or more gaps between temperature-controlled rolls. Numerous stretching machines are available; they differ with respect to the number and arrangement of the rolls. Monoaxial stretching is of particular importance in the manufacture of high-strength tape from polyethylene and polypropylene, as well as for the orientation of poly(vinyl chloride), polycarbonate, and poly(vinylidene fluoride) films. Longitudinal stretching units are also incorporated in film production lines that employ sequential stretching technology for the manufacture of biaxially oriented films (see Section 2.3.2).

2.3.2. Biaxial Stretching

Sequential Stretching. Sequential biaxial stretching is currently the preferred orienting method for example with polyester and polypropylene films. Figure 6 illustrates a production

line that uses longitudinal–lateral stretching (the so-called machine direction–transverse direction, MD−TD sequence) for the manufacture of biaxially stretched film. The film line consists essentially of a chill roll facility coupled with forward and transverse stretching units.

The polymer is first dried, melted in an extruder, passed through a slot die, and vitrified on a chill roll. Longitudinal stretching follows using a system of rollers, whereas drawing in the transverse direction occurs in an air-heated oven (stenter) comprising several temperature-controlled zones. When the longitudinally stretched film enters the stenter, it is grasped at both edges by two series of continuously circulating clips which are linked together in a chain. In the zone where the film reaches the stretching temperature, the two series of parallel-running clips are gradually drawn apart and hence stretch the film in the transverse direction (Fig. 6). The film is then heat-set (crystallized), cooled, released from the clips, and wound to a roll. Draw ratios for polyester lie typically between 3 : 1 and 4 : 1 [9], [10].

Facilities for edge-trimming, thickness determination, and, where appropriate, corona treatment (see Section 2.4.1) are located between the stenter and the winding unit. Winding speeds range from 80 to 250 m/min. Film thickness varies from 1 to 350 μm.

Polyester films with a high modulus of elasticity in the machine direction are best prepared by a TD−MD stretching sequence, or in a three-step process with MD−TD−MD stretching.

Simultaneous Stretching. Simultaneous biaxial orientation is most easily achieved by inflation of a tubular film. In the continuous process, a tube is first created by cooling the melt in a water bath or with a cooling mandrel. This tube is subsequently heated to the stretching temperature with a ring of radiant heaters. It is then inflated, collapsed, and transported as described for blown films (see Section 2.2.2). This technique is widely used for preparing biaxially oriented poly(vinylidene chloride), polyamide, polyester, and especially polypropylene tubular films; all of these films have a high shrinking potential. For this reason, oriented polypropylene tubular films are normally slit, separated, and then heat-set, either with the aid of heated rollers or in a hot-air tunnel.

Simultaneous biaxial stretching of a flat film is technically more complicated than that of tubular materials. Normally, a special stretching (stenter) frame is used in which the clips are not linked in a chain as described for sequential stretching. The clips are individually accelerated as they pass through the transverse-stretching zone by means of a progressive transport system.

2.4. Film Modification and Converting

Films are normally intermediates from which end products are manufactured in subsequent processing steps. The terms *film modification* and *converting* refer to operations such as surface treatment, coating, or lamination, which enhance the value of a film. Commonly encountered end products derived from films include packaging materials (e.g., printed bags and adhesive tapes), capacitors, magnetic tapes, and photographic films.

Untreated films often lack the specific characteristics that are required in the final product, e.g., stability during handling, heat sealability, wettability, adhesion of printing ink or other coatings, and barrier properties. Further processing is then needed to remedy these deficiencies. Sometimes the desired results can be obtained with additives (cf. Chap. 3), which include antistatic agents and lubricants. However, surface treatment or coating is often necessary, and in some cases two or more films must be combined to form a laminate.

2.4.1. Corona Treatment

Corona treatment is the principal method of preparing a film surface for printing or coating. A continuously moving film is exposed to an ionized atmosphere, which is produced by an alternating electrical field [11]. The changes induced in the film surface enhance both its wettability and adhesion properties. Corona treaters can be integrated into the film production process (see Sections 2.2.2 and 2.3.2) and are widely utilized in the pretreatment of polyolefin films.

2.4.2. Coating

Films may be coated with dissolved, dispersed, emulsified, or molten materials [8], [12]. The techniques employed differ considerably, depending on whether the material is applied as a liquid or as a melt.

Liquid materials are normally coated on one or both sides of a moving film web either by immersion or with the aid of applicator rolls. The coated film is then dried in a heated-air oven or by means of rollers.

Coating is normally performed separately from film production (*off-line coating*), although in some special cases, the two processes can be integrated (*in-line coating*) [13]. In in-line coating (e.g., of polyester films), the coating assemblies are preferentially placed between the MD and TD stretching units.

Coating materials such as nitrocellulose, polyacrylates, and poly(vinylidene chloride) are used to improve heat sealability and gas barrier properties. Adhesion is improved by coating films with polyurethanes, cross-linkable polyacrylate, copolyesters, or epoxides. Other coatings include antistatic or slip agents, scratchresistant and antiadhesive materials.

Films with a different functional coating on each surface possess a combination of properties (e.g., sealing and barrier properties) and can be produced on a large scale.

Molten materials are applied to films with the aid of a die by a process analogous to chill extrusion (see Section 2.2.2). The film itself is supported by a roller. Extrusion coating can be conducted either off- or in-line; the latter approach is employed with biaxially stretched films.

Coextrusion represents a special case of melt coating [14], [15] in which two or more polymer melt streams are combined either in the melt pipes or in a multimanifold die just before the material emerges from the die lips. In the former case, special adapters of varying design ensure that the melt streams do not mix in the die and hence leave the die gap in the form of a multilayer film analogous to that produced by a multimanifold die. This process is also adaptable to annular die systems.

Coextrusion has gained considerable importance. Sealable, biaxially oriented polypropylene film with a triple-layer structure is a particularly important product in the packaging indus-

try. The thickness of the sealable layer is typically 0.5 µm.

Coextruded, double-layer films are commonly employed for magnetic tape and capacitors; they have a smooth side which can be coated, and a rough side, which ensures a low coefficient of friction for adequate processability.

2.4.3. Lamination [8], [12]

Two or more different films can be bonded to form a composite or multilayer film. Their individual properties are thus combined, resulting in a variety of high-quality materials for both the packaging industry and the technical sector. For example, a heat-sealable film may be laminated to a film that acts as a barrier to gases and/or to a high-strength film. The potential number of property combinations is very large.

Laminated composite films are commonly prepared by the *dry lamination process,* in which a dissolved or dispersed adhesive is coated on the surface of the film. After evaporation of the solvent in a dryer, the coated film is bonded to a second film web in a laminating unit consisting of a pair of nip rolls, one made of rubber and the other of steel.

The simplest laminating system is composed of two unwinding stations, an adhesive applicator, a dryer, a laminating unit, and a windup station. However, many different systems are in use, depending on the desired number of laminate layers and the choice of adhesive. In some cases, adhesion can be achieved without using solvents, e.g., by using hot melts, reactive adhesives, or systems that can be hardened by irradiation.

3. Additives

Nearly all films contain additives which perform two main functions: (1) stabilization of the polymers and (2) improvement of processability and the potential uses of the film [16], [17] (see also → Plastics, Additives, → Plasticizers).

Additives can be introduced when the polymer is being prepared or processed, or during film production. An additive must withstand all stages of processing without any loss of activity. Additives used in films that come into contact with food must also comply with legal health and safety requirements.

Processing Stabilizers. The thermal decomposition of some film raw materials must be suppressed by addition of processing stabilizers so that the melt can be thermoformed. The choice of stabilizer depends on the decomposition mechanism involved. Thus, sterically hindered phenols effectively stabilize polypropylene, while poly(vinyl chloride) responds to treatment with metal salts (in particular organic tin salts) or *N,N′*-diphenylthiourea [*102-08-9*]. Additive concentrations range from <1 to 3 wt %.

Plasticizers. Plasticizers are particularly useful for adjusting the flexibility of poly(vinyl chloride), cellulose acetate, and cellulose hydrate films. The plasticizer concentration may be as high as 40 % (plasticized PVC); typical examples include esters of phthalic and phosphoric acids.

Slip or Antiblocking Agents. Films with smooth surfaces possess a high coefficient of friction and therefore tend to block during winding and other processing operations. To improve the frictional properties of these films, their surface is finely structured by adding small amounts of finely dispersed pigments. The surface of biaxially oriented polyester films can be improved by adding inert inorganic pigments (e.g., calcium carbonate, silicon dioxide, or calcium phosphate) or particles composed of crosslinked polyacrylates. The particles are < 1 µm in diameter, and are used at a concentration of < 0.5 wt %. Lubricants such as fatty amides or polysiloxanes may also be introduced.

Fillers and Dyes. The optical properties of films can be altered by the incorporation of fillers and dyes. A wide range of concentrations is employed. Many fillers are inert inorganic substances, e.g., titanium dioxide, barium sulfate, kaolin, and carbon black. Colored films are normally produced from raw materials that have been dyed in bulk. However, in special cases the films themselves may be dyed either by a diffusion process or by printing the entire surface.

Antistatic Agents. Films are rendered antistatic by mixing the virgin polymer with a substance bearing hydrophilic groups. The additive migrates to the surface layer. Quaternary ammonium compounds, ethyl sulfonates and, especially with polyolefin films, ethoxylated alkyl amines are used as antistatic agents.

Weathering Stabilizers. Most films for outdoor applications are prone to photooxidative degradation and are stabilized by adding UV-absorbing substances. Piperidyl derivatives, for example, are effective stabilizers of polypropylene.

4. Delivery Forms

Commercial quantities of films are available in various thicknesses (ca. 1 – 1000 µm) and are supplied in the form of rolls with cores of a standard diameter (e.g., 6″).

Standardized thicknesses are demanded for many applications. Attempts are being made to establish a standardized system, since this also simplifies production planning and stock control. Films are offered in widths ranging from a few millimeters to several meters. Standard widths have only been established in a few areas of application.

The maximum length of a film depends on the intended application as well as on the film thickness. For example, with poly(ethylene terephthalate) (PETP), films with a thickness of 5 µm are supplied in rolls with a typical length of 30 km.

Films that are precut to size are also marketed, although only to a very limited extent.

5. Test Methods [18–24]

Many of the test methods employed for process control in film manufacture have been standardized. However, the results obtained are not always compatible because the test conditions specified in different standards often vary.

The *chemical composition* of a film is normally apparent from its IR spectrum. Trace elements are determined by atomic absorption spectroscopy, mass spectrometry, or neutron activation analysis. Relative molecular masses can be measured from the viscosity of a film solution. The identity of a film can often be determined more simply with the aid of systematic analytical schemes (e.g., [20], Appendix B).

The *average thickness* of a film is established according to DIN 53 370 or ASTM E 252. No standard method for measuring thickness in both the machine and transverse directions exists as yet. During manufacture, film thickness can be determined by measuring the absorption of either β- or IR radiation or by a dielectric method. The uniformity of the thickness of a film sample can be determined mechanically, electrically, or optically. The accuracy of measurement in all cases is 0.1 µm.

Methods for determining the *mechanical properties* of films are described in ASTM D 882, D 1822, D 1894, D 1922; ISO 1184 (1983). Individual methods are as follows: tear strength, DIN 53 455; elongation at break, DIN 53 457; modulus of elasticity, DIN 53 448; impact strength, DIN 53 374; tear resistance, DIN 53 375; and tear propagation resistance, DIN 40 634 and DIN 53 363.

The *coefficient of friction* is of considerable importance in the converting of films, and conventional methods for its determination are described in DIN 53 375 and ASTM D 1894. Special techniques have been developed for some applications (e.g., for magnetic tapes).

Film density is determined according to ASTM 1505 IC.

The *electrical properties* of films are tested according to VDE 0345/1.65 and 0303/7/1.65; ASTM D 149, D 150, D 229, and D 252; and DIN/sec 15 C. Parameters that are measured include the dielectric strength, dielectric constant, dissipation factor, resistivity, surface resistance, electrolytic corrosion, and glow discharge ignition voltage.

The melting point, glass transition temperature, crystallization and *softening behavior,* and *decomposition temperature* are easily determined by differential thermal analysis. The *long-term thermal stability* of films designed for use as electrical insulators is normally determined according to VDE 0530 or IEC 216; the films can then be classified according to the temperature at which they may be used, i.e., Class T (90 °C), A (105 °C), E (120 °C), B (130 °C), F (155 °C), H (180 °C), and C (> 180 °C).

The coefficient of expansion, dimensional stability, and *thermal conductivity* can be determined by reference to the following standards, which are not, however, exclusively designed for films: DIN 1341, 40 634, 52 328; ASTM D 229, D 1204; VDE 0530/1/1.66.

The following standards apply to the measurement of *optical properties* (transparency, haze, gloss, refractive index, and color): DIN 5033, 53 491; ASTM 1003, D 307, D 1925, D 2457. The measurements are easy to perform, but interpretation of the results can be difficult.

Determination of *permeability* with respect to liquids, vapors, and gases is relatively complicated, but this parameter is especially valuable, since films are widely used as packaging materials. Appropriate procedures are described in DIN 53 122 and 53 386, and ASTM D 1434 and E 96 (E).

Chemical resistance is most easily determined by examining the changes induced in ultimate strength and elongation at break as a result of exposure to the substances concerned. However, the following standards are also applicable: DIN 53 476; ASTM D 543, D 756, D 1435, E 96; ISO/R 175 and R 511.

Water absorption is determined according to DIN 53 472 and ASTM 0570.

The most useful test of *surface structure* is carried out with a profilometer. Since the 1980s this technique has proved itself to be particularly useful for examining film substrates used in the manufacture of magnetic tapes. The best known procedures are those described in DIN 4760 – 4774, the Japanese Industry Standard JIS 0601-70, and ISO/DIS 4267/1. In special circumstances, additional information can be obtained by using microscopy (interference methods and scanning electron microscopy).

The *roll hardness* of film rolls can be evaluated by using the Shore hardness as a criterion (DIN 53 505, ISO 12 868). A better procedure makes use of a falling sphere [24].

The *flammability* of films is evaluated according to DIN 4102, ASTM D 1433, ISO R 1715, and Underwriters Laboratory Standard UL 94 VTM.

Measurement of the *extraction of low molecular mass components* of films with solvents has not been standardized. Most studies are based on special procedures developed by individual manufacturers and end users. Interest centers on films designed for the packaging industry. Information regarding the extractable components of a film often serves as the basic for its legal approval (e.g., FDA approval) [25].

6. Film Products [20], [26], [27]

A remarkable variety of film materials has been developed as a result of several factors: Film manufacturers have a wide choice of potential raw materials and can also use special processing steps such as stretching to modify certain properties of a film during its manufacture. Further variants are made possible by the introduction of additives, by the application of functional coatings, or by lamination of two or more types of film. The following discussion is limited to representative examples from characteristic film groups. Important physical properties of these materials are compiled in Tables 2, 3, 4, 5. (The lists of trade names supplied are by no means exhaustive.)

6.1. Cellulose Derivatives

6.1.1. Cellulose Hydrate (→ Cellulose, Chap. 3.1.)

Cellophane [*9005-81-6*] is a trade name applied to films based on cellulose hydrate (regenerated cellulose).

Cellophane is prepared from cellulose via the sodium xanthate derivative in a solution casting process (see Section 2.1) and is available in thicknesses ranging from 12 to 45 µm. Untreated cellophane film is crystal clear, glossy, and highly permeable to water vapor; it is unstable with respect to water, but stable to fats and oils. Cellophane is not heat-sealable, but can be bonded; it is odorless, tasteless, and authorized for use as a food packaging material by the FDA and similar institutions. It possesses desirable mechanical characteristics at the normal water content of 7 – 8 %. Properties are listed in Table 2.

Cellophane is increasingly being replaced by oriented polypropylene films; 70 – 80 % of its original applications (mainly in packaging) have already been affected.

Table 2. Properties of selected films [a]

Manufacturers. Wolff Walsrode, Federal Republic of Germany; Chemiefaser Lenzing, Austria; British Cellophane, United Kingdom; Flexel, Atlanta, United States; Futamura, Japan.

6.1.2. Cellulose Esters (→ Cellulose Esters)

Films derived from cellulose acetate [*9004-35-7*] (CA) (2-acetate, 2 1/2-acetate, and 3-acetate), cellulose acetate propionate [*9004-39-1*] (CAP), and cellulose acetate butyrate [*9004-36-8*] (CAB) are available; they all contain plasticizers–phthalate esters, aliphatic alcohols, triphenyl phosphate. Solution casting is the usual production method. Methylene chloride [*75-09-2*] is used as a solvent [9]. The casting solution has a cellulose acetate concentration of 18 – 26 % and a viscosity of 15 – 30 Pa · s.

Cellulose acetate films are the most important of the cellulose ester films. The properties of cellulose acetate vary as a function of the number of acetate groups per cellulose molecule. The properties of cellulose acetate film (2 1/2 acetate) are listed in Table 2. Films with the highest acetate concentration, corresponding to the minimum number of hydroxyl groups, show reduced sensitivity to moisture as well as minimal absorption of water and low water-vapor permeability. These films are crystal clear in their untreated state; they are dimensionally stable at ambient temperature and humidity and possess good electrical properties. Special surface characteristics (e.g., gloss, roughness) can be conferred during manufacture by casting on an appropriate type of metal belt.

Cellulose acetate films are used as supports for photographic coatings, as transparent windows, release films, decorative materials, and as electrical insulators.

Trade Names. Acetatfolie (Hoechst, Federal Republic of Germany); Triafol (Bayer, Federal Republic of Germany); Ultraphan (Lonza, Federal Republic of Germany); Bexoid (Bexford, United Kingdom); Cellittor (British Cellophane, United Kingdom).

6.2. Hydrocarbon Polymers

6.2.1. Low-Density Polyethylene (LDPE) (→ Polyolefins)

Low-density polyethylene [*9002-88-4*] (LDPE) has a molecular mass of > 50 000 and is prepared by the high-pressure process. It is converted into film mainly by the film blowing process at a melt temperature of 150 – 210 °C. For properties of the film, see Table 2.

Film thickness of LDPE ranges between 25 and 200 µm. The films are transparent to crystal clear, depending on the choice of relative molecular mass and process technology. They are soft, flexible, and resistant to creases and show high tear and tear propagation resistance. Mechanical properties are stable at low temperature and chemical resistance is very high. Films made from LDPE display low permeability to water vapor but high permeability to gases. They are nontoxic and contain neither plasticizers nor odorous materials. Low-density polyethylene films are easily welded and thermoformed. Specific shrinking characteristics can be imparted to the films by stretching at low temperature.

Films made from LDPE are used for packaging and as protective coverings. They are also employed in the production of composite films. Low-density polyethylene has become commercially important. Worldwide annual production is estimated at more than 8×10^6 t.

Trade Names. Plastotrans (Folienfabrik Forchheim, Federal Republic of Germany); Waloplast (Wolff Walsrode, Federal Republic of Germany); Helioflex (Feldmühle, Federal Republic of Germany); Bexthene (Bexford, United Kingdom); Cryovac L (Cryovac Div., W. R. Grace, United States).

Film derived from a copolymer of ethylene with vinyl acetate (EVM film) is used similarly as a packaging material. Its exceptional adhesive properties make it particularly suitable as a cling and stretch-wrap film.

Trade Name. Montothene (American Can, United States).

6.2.2. High-Density Polyethylene (HDPE) (→ Polyolefins)

High-density polyethylene [*9002-88-4*] (HDPE) prepared by the low-pressure method is also gaining importance as a raw material for films. Films made from HDPE are produced both by chill roll extrusion and by film blowing. Characteristics of the films are given in Table 2.

Films derived from HDPE have a higher chemical resistance than LDPE films and can be employed over a somewhat wider temperature range; HDPE films are used in construction and civil engineering as insulators. High-density polyethylene film can be welded and bonded, and is readily thermoformable.

Trade Names. Plastin (Folienfabrik Forchheim, Federal Republic of Germany); Fortiflex (Crown Zellerbach, United States).

Polyolefins (mainly HDPE) are the basis of several types of "synthetic paper," which are also prepared by film-forming techniques. The market for this material in Great Britain in 1985 was estimated to be 40 000 t/a.

6.2.3. Linear Low-Density Polyethylene (LLDPE) (→ Polyolefins)

The 1980s witnessed the development of films derived from linear low-density polyethylene (LLDPE), which are produced in the same way as LDPE films. Linear low-density polyethylene films have better mechanical properties (greater strength and higher ultimate strength) than ordinary LDPE films. As a result, LLDPE films have found applications as sacks for transporting heavy materials. Since LLDPE also has a higher melting point (118 °C) than LDPE (110 °C), these sacks can be filled with hot materials (e.g., freshly produced cement). Stretch-wrap packaging represents another expanding market. Like other polyethylene films, LLDPE films can be combined with additional materials to form composite films.

6.2.4. Polypropylene (PP) (→ Polyolefins)

Polypropylene [*9003-07-0*] (PP) film is available in an unoriented form as well as in both mono- and biaxially oriented versions.

Unstretched PP film is prepared either by chill roll casting or by blowing. Its properties are comparable to those of LDPE film, but with the advantages of greater transparency and a wider application temperature range. Unstretched PP film is used exclusively for packaging purposes. West European consumption in 1986 was 80 000 t.

Monoaxially stretched PP film exhibits increased strength in the direction of orientation and is used for three major applications: (1) cable insulation, (2) tapes and industrial fabrics, and (3) yarns and ropes.

Biaxially oriented polypropylene (*BOPP*) *film* is the most important type of polypropylene film; its properties are listed in Table 2. Worldwide consumption in 1986 was 550 000 t of which 460 000 t could be attributed to the packaging industry and 60 000 t to the technical sector. An additional 30 000 t was processed into adhesive tapes. Films made of BOPP currently occupy ca. 80 % of the packaging market once held by cellophane. Factors contributing to this development include superior properties, lower cost, and an ecologically preferable manufacturing technology. Likewise, glassine (a thick semitransparent greaseproof paper) is being replaced by opaque BOPP films that are heat- and cold-sealable. These films were introduced in the late 1970s by Hoechst [28].

Biaxial orientation can be achieved by any of the standard methods (see Section 2.3.2), but sequential stretching is preferred because this method permits a wide range of thicknesses. Most BOPP packaging films are provided with a separate sealing layer, formed either by coextrusion or in an off-line coating process. Coextruded sealing coatings normally consist of polyolefin copolymers, whereas polyacrylate or poly(vinylidene chloride) is used for off-line coating. Poly(vinylidene chloride) has the added advantage that it simultaneously improves the oxygen barrier properties of the film.

Biaxially oriented polypropylene films range in thickness from 4 to 80 µm. They are used industrially in laminates and as release and capacitor films.

Trade Names. Trespaphan (Hoechst, Federal Republic of Germany); Propafilm (ICI, United Kingdom); Shorco (British Cellophane, United Kingdom); Walothen (Wolff Walsrode, Federal

Republic of Germany); Bicor (Mobil, Belgium); Moplefan (Montedison, Italy).

6.2.5. Poly(4-methyl-1-pentene) (PMP) [29] (→ Polyolefins)

Poly(4-methyl-1-pentene) [*9016-80-2*] (PMP) films are produced by extrusion and possess the lowest density of all available films (0.83 g/cm^3). They have a higher softening point (*mp* 240 °C) than PP films (*mp* 165 °C). Film thickness ranges from 50 to 300 µm. For properties, see Table 2.

PMP films have been used only in combination with other materials, mainly with cardboard for the packaging of oven-ready meals.

6.2.6. Ionomers (→ Specialty Plastics)

The term *ionomer* describes a family of polymers incorporating both covalent and ionic bonds. Ionomers [*25608-26-8*] are based on polyethylene and have carboxyl groups located along their polymer chains. These groups provide ionic cross-links between chains [20]. The corresponding films are prepared by extrusion.

Many of the properties of ionomer films are comparable to those of LDPE films. However, ionomer films are more resistant at room temperature to fats and oils than LDPE films, and they possess exceptionally good sealing properties. They are also extremely tough and are ideally suited for packaging.

Trade Name. Surlyn A (Du Pont, United States).

6.2.7. Polystyrene (PS) (→ Polystyrene and Styrene Copolymers)

Polystyrene [*9003-53-6*] (PS) films are available in unoriented as well as in mono- and biaxially stretched form. They are produced by chill roll extrusion or by blowing. For properties, see Table 3. For foamed PS films see →Foamed Plastics, Chap. 4.2.2.

Oriented films are crystal clear with a high gloss but are extremely brittle. Their most important application is for envelope windows. The polymer must be modified with synthetic rubber to increase its strength. However, the resulting increase in impact strength is obtained at the expense of reduced transparency. Film thicknesses are between 4 and 500 µm.

The favorable dielectric characteristics of PS film result in its use in high-voltage capacitors and as an insulator for cables.

Trade Names. Styroflex (Norddeutsche Seekabelwerke, Federal Republic of Germany); Trycite (Dow Chemical, United States).

6.3. Halogenated Hydrocarbon Polymers

6.3.1. Poly(Vinyl Chloride) (PVC) [6] [→ Poly(Vinyl Chloride)]

Films formed from poly(vinyl chloride) [*9002-86-2*] (PVC) may be either rigid or flexible. Rigid films consist solely of PVC; flexible films are produced by addition of plasticizers or by copolymerization with acrylate esters or vinyl acetate. Both rigid and plasticized PVC films are produced by calendering processes, although chill roll casting and film blowing are also possible. Some PVC films are also subjected to stretching.

Rigid and plasticized PVC films are of great economic importance. Worldwide production is estimated at 1.4×10^6 t/a.

6.3.1.1. Rigid PVC

Rigid PVC film is available in a wide range of thicknesses (30 – 700 µm); important properties are listed in Table 3. The material varies from crystal clear to transparent and may be colored by the addition of pigments. Rigid PVC is unaffected by water and is virtually impermeable to odors. It possesses outstanding chemical resistance and is also highly flame resistant. The film can be welded, heat-sealed, embossed, thermoformed, stamped, bonded, imprinted, and (under high vacuum) metallized. These remarkable properties combine to produce a broad spectrum of applications for rigid PVC film both in packaging and the industrial sector. Adhesive tapes account for a particularly large share of the market.

6.3.1.2. Plasticized PVC

Plasticized PVC films have an even wider range of applications than rigid PVC because the properties of plasticized PVC can be modified by varying the type and amount of plasticizer added. Plasticized PVC films are available with a thickness of 10 – 1000 µm; for important properties, see Table 3. The material can be strained and shows little tendency to wrinkle; its consistency varies from soft to hard. Plasticized PVC film is resistant to both tear and tear propagation, and it can be embossed, welded, bonded, and stitched. It is resistant to most inorganic and organic chemicals, as well as to water and light. It also shows good aging and weathering properties. Permeability to water vapor and gases is minimal.

Plasticized PVC film is used mainly in packaging and the building industry, as a protective covering, in laminated films, and for the modification of wood surfaces. It is also processed into commercial adhesive tapes.

Trade Names. Genotherm, Guttagena, Genopak, Suprotherm (Hoechst, Federal Republic of Germany); Mipolam (Dynamit, Federal Republic of Germany); Folan, Polytherm (Folienfabrik Forchheim (Federal Republic of Germany); Pentafilm (Pentaplast, United States).

6.3.2. Poly(Vinylidene Chloride) (PVDC)

[27], [30] [→ Poly(Vinylidene Chloride)]

Poly(vinylidene chloride) [*9002-85-1*] (PVDC) films are made from a vinylidene chloride–vinyl chloride–vinyl acetate copolymer [*9003-20-7*]. The comonomers render the product sufficiently stable for extrusion. Plasticizers are also added to improve processing properties. The films are manufactured by the tubular drawing process. Since the stability of the melt is low, the film tube must be cooled as it emerges from the die prior to orientation by blowing (see Section 2.3.2). For properties, see Table 3.

Poly(vinylidene chloride) film has been on the market under the trade name Saran since the late 1940s and is still widely used because of its outstanding water vapor and oxygen barrier properties. Its principal application is in the packaging of perishable foodstuffs.

The material is supplied as a shrinkable monofilm or coextruded film; PVDC laminates are also available. Coextruded products are prepared in both tubular and flat form. The PVDC generally is sandwiched between other polymeric layers which impart strength and toughness. Adhesion problems are overcome by simultaneously extruding an adhesive tie layer.

Trade Names. Saran, Saranex (Dow Chemical, United States); Cryovac (Grace, United States); Krehalon (Kureha, Japan); Supralon (Asahi, Japan).

6.3.3. Fluoropolymers [26]

(→ Fluoropolymers , Organic)

Incorporation of fluorine into hydrocarbon chains results in polymers that display antiadhesive characteristics, thermal stability, flame resistance, insulating properties, and, most important of all, extreme stability with respect to weathering and aggressive media. As a result of these properties, which depend on the degree of substitution, these films are used mainly under extreme conditions.

From a chemical standpoint, the fluoropolymers used for film production fall into three categories:

1) perfluorinated polymers,
2) partially fluorinated polymers,
3) polymers containing chlorine as well as fluorine

Polytetrafluoroethylene (PTFE) is a perfluorinated polymer that cannot be processed from a melt by conventional techniques. Polytetrafluoroethylene films are prepared by isostatically sintering the powdered material, followed by "skiving" (paring) of the sintered block. All other fluoropolymers–including copolymers of PTFE with perfluorinated vinyl components–are extrudable and can, therefore, be made into films either by the chill roll process or by film blowing.

The market for fluoropolymer films in the United States is dominated by films made from poly(vinyl fluoride) (PVF), PTFE and polychlorotrifluoroethylene (PCTFE). Extrudable copolymer films made from tetrafluoroethylene–hexafluoropropylene copolymer (FEP),

perfluoroalkoxy polymer (PFA), and ethylene–tetrafluoroethylene copolymer (ETFE) have also become somewhat important, or at least have a considerable potential for development. Film made of poly(vinylidene fluoride) (PVDF) is also worth mentioning because of its piezoelectric properties.

6.3.3.1. Poly(Vinyl Fluoride) (PVF)

Poly(vinyl fluoride) [*24981-14-4*] (PVF) film is commercially available in both transparent and pigmented form in thicknesses of 12 – 50 µm. For properties, see Table 3. Its antiadhesive characteristics, together with its resistance to mechanical, chemical, and weathering effects, make PVF film suitable for use as a protective lamination on both interior and exterior paneling. It also serves as a release film in the pressing of synthetic resin.
Trade Name. Tedlar (Du Pont, United States).

6.3.3.2. Poly(Vinylidene Fluoride) (PVDF) [31]

Poly(vinylidene fluoride) [*24937-79-9*] (PVDF) films are solvent cast or extruded with a thickness of 50 –500 µm. They possess excellent resistance to weathering and aggressive media.

Poly(vinylidene fluoride) film has an exceptionally high dielectric constant and a relatively high dissipation factor. Because of its piezoelectric properties, the monoaxially stretched film is often employed as a mechanical–electrical transducer in membranes. The consumption of film for piezoelectric applications is small (ca. 1 t); its price is extremely high.
Trade Name. Fluorex (Rexham, United States); Kynar (Pennwald, United States).

6.3.3.3. Polytetrafluoroethylene (PTFE)

Polytetrafluoroethylene [*9002-84-0*] (PTFE) films have the highest resistance to aggressive agents of any polymer film and are thermally stable up to 250 °C. Since PTFE films are produced via sintering and skiving, they are somewhat porous; some properties are listed in Table 3. Most of the PTFE film that is produced is used for sealing pipe joints and flanges.

Two related copolymers are extrudable: FEP [*25036-53-7*], derived from tetrafluoroethylene and hexafluoropropylene, and PFA [*2645-79-6*], a copolymer of tetrafluoroethylene and a perfluorovinyl ether. Films produced from these materials are not porous, but otherwise display essentially the same characteristics as PTFE itself. The mechanical and optical properties of the extruded films are superior to those of skived PTFE films. Commercial products are available in thicknesses from 12 –1000 µm. Their principal uses are as release films, in the electrical industry, and especially as container linings.
Trade Name. Hostaflon (Hoechst, Federal Republic of Germany); Teflon (Du Pont, United States); Fluon (ICI, United Kingdom).

6.3.3.4. Polychlorotrifluoroethylene (PCTFE)

Films made from polychlorotrifluoroethylene [*9002-83-9*] (PCTFE) are used widely in the packaging of pharmaceuticals and medical supplies; this is because the films possess excellent moisture barrier properties and chemical resistance, coupled with good processability, sterilizability, and UV stability. These films are available in thicknesses ranging from 12 to 250 µm.
Trade Name. Aclar (Allied, United States).

6.4. Poly(Methyl Methacrylate) (PMMA) [32] (→ Polyacrylates)

Poly(methyl methacrylate) [*9011-14-7*] (PMMA) films are prepared either by chill roll extrusion or by film blowing; thicknesses range from 50 to 500 µm. They show high resistance to heat and weathering, but their ultimate strength and elongation at break are relatively low. For properties, see Table 4.

Poly(methyl methacrylate) film is frequently used as a protective layer on metal and plastic, thereby competing with PVF film.
Trade Name. Korad (Polymer Extruded Products, United States); Plexiglas-Folie (Röhm, Federal Republic of Germany); Shinkolite Film (Mitsubishi Rayon, Japan).

6.5. Poly(Vinyl Alcohol) (PVA) [33]

(→ Polyvinyl Compounds, Other)

Poly(vinyl alcohol) [*9002-89-5*] (PVA) is produced by hydrolyzing poly(vinyl acetate). Both the fully and partially hydrolyzed polymers are utilized for film manufacture; the fully hydrolyzed polymer is water-soluble.

Poly(vinyl alcohol) film can be prepared by casting an aqueous PVA solution or by extrusion. Prior to extrusion, the poly(vinyl alcohol) is compounded into a paste with water and a plasticizer. Film thicknesses are in the range of 20 – 75 µm.

The characteristic features of PVA film include its high transparency and gloss, toughness, absence of static charge, and, in the absence of moisture, desirable oxygen barrier properties. Water solubility varies, depending on the vinyl acetate content.

Poly(vinyl alcohol) is employed as a monofilm, but can also be coated with PVDC or laminated with polyolefins. Biaxially oriented films can be produced by simultaneous stretching [34].

Poly(vinyl alcohol) films are used as packaging materials for food, textiles, and as release films in the manufacture of synthetic resin products. They are also employed in the manufacture of water-soluble sachets for disposable packaging of hygienic products and as a basis for polarized films.

Trade Names. Vinylon (Kuraray, Japan); Emblar-OV (Unitika, Japan); Bovlon (Nippon Gohsei, Japan).

6.6. Ethylene–Vinyl Alcohol Copolymer (EVOH)

A partially crystalline copolymer of ethylene and vinyl alcohol, EVOH [*25067-34-9*] is prepared by hydrolysis of an ethylene–vinyl acetate copolymer. This material first appeared on the market in the 1970s [35]; it can be processed into a film by extrusion.

Films derived from EVOH are excellent gas barriers. Biaxial orientation leads to increased strength and further reduction of gas permeability. Since the gas barrier properties of EVOH films are adversely affected by moisture, they are primarily used in the form of laminates or coextrudates. Some properties of oriented EVOH film are listed in Table 4.

The principal application of these materials is in food packaging.

Trade Names. Eval (Kuraray, Japan); Exceed (Okura, Japan).

6.7. Polyamide (PA) [20] (→ Polyamides)

Polyamide (PA) films (thickness 12 – 25 µm) are made mainly from nylon 6 [*25038-54-4*] and nylon 66 [*32131-17-2*] by chill roll extrusion or film blowing. The films display high tensile and tear strengths, as well as high resistance to puncture, abrasion, oils, and fats. Nylon films have a low permeability to gases, depending on the atmospheric humidity. Nylon 11 [*25035-04-5*] and nylon 12 [*24937-16-4*] are used for films with lower water-vapor permeability.

Orientation improves the properties of nylon films. Biaxially oriented films are produced from nylon 6 by simultaneous stretching. Properties of these films are listed in Table 4.

Polyamide films are used as monofilms but are employed mainly in composite structures produced by lamination, extrusion coating, or coextrusion with sealing or barrier resins.

Trade Names. Capran (Allied, United States); Dartek (Du Pont, United States); Bonyl (Kohjin, Japan); Emblem (Unitika, Japan); Supronyl (Hoechst, Federal Republic of Germany).

6.8. Polyester [10] (→ Polyesters)

The term *polyester film* generally refers to films prepared from poly(ethylene terephthalate) [*25038-59-9*] (PETP). However, other polyesters are also processed into film, e.g., poly(butylene terephthalate) [*24968-12-5*] (PBT) and poly(ethylene-2,6-naphthalene dicarboxylate) [*24968-11-4*] (PEN) (trade name: Q-Film, Teijin/Japan) [36].

Polyester films are manufactured by extrusion; the majority are biaxially oriented and produced in flat form; only a small amount of tubular film is made.

Biaxially oriented PETP films are prepared in thicknesses ranging from 1.0 to 350 µm and vary in appearance from clear to transparent, depending on their end use. Pigments can also be added for coloration.

Polyester films have favorable mechanical and electrical properties, are resistant to solvents, and display long-term thermal stability up to 130 °C (VDE 0530). They can be welded and bonded by special techniques. Furthermore, these films can be printed by flexographic, gravure, and screen printing techniques; they are also suitable for high-vacuum metallization without the need for special pretreatment. Some polyester films can be subjected to further deforming subsequent to their manufacture, for example, by thermoforming or thermally induced shrinking. Properties of PETP film are listed in Table 4; its permeability to gases and water vapor can be significantly decreased by coating with PVDC.

Polyester films are used for more applications than any other type of film. They are employed as packaging materials, dielectrics, and electrical insulators, as base films for photographic and magnetic coatings, as release films in synthetic resin moldings, and as color and montage film in the graphics industry. These films also serve as a base for flexible printed circuits, as drafting films, and as decorative film. Polyester films have gained considerable importance in the manufacture of videotapes. The demand for polyester film as a base for thermal transfer tapes is also increasing.

Polyester films can be combined with other materials (PE film, paper webs, and aluminum foil) to produce excellent composites.

The economic importance of polyester film is formidable: 550 000 t was sold worldwide in 1986, most of this being used in the manufacture of electrical insulation, magnetic tape, photographic film, and packaging film.

Trade Names. Hostaphan (Hoechst, Federal Republic of Germany); Mylar (Du Pont, United States); Melinex (ICI, United Kingdom); Lumirror (Toray, Japan); Tetoron (Teijin, Japan); Diafoil (Diafoil, Japan); Terphane (Rhône Poulenc, France); Espet (Toyobo, Japan).

6.9. Polycarbonate (PC) [20]

(→ Polycarbonates)

Polycarbonate [*25037-45-0*] (PC) film first appeared on the market in 1957 and is prepared from bisphenol A and phosgene. The principal manufacturers of both polycarbonate and polycarbonate film are General Electric and Bayer.

Polycarbonate films are produced either by extrusion (chill roll) or by solution casting and are available with a thickness of 2 – 500 µm. The thinner grades are subjected to monoaxial stretching. The properties of monoaxially stretched PC film are listed in Table 4.

The special characteristics of these films include their sterilizability, dimensional stability, thermoformability, and long-term thermal stability up to 130 °C (VDE 0530). They are transparent to crystal clear in appearance, and possess good electrical properties. Applications have been found in packaging, the electrical industry, and above all in the field of graphics. Consumption of PC film in the United States is ca. 3000 t/a.

Increased usage is anticipated, partly as a result of new developments in the raw material sector.

Trade Names. Lexan (General Electric, United States); Makrofol (Bayer, Federal Republic of Germany); Pokalon (Lonza, Federal Republic of Germany).

6.10. Polysulfone (PSU) (→ Specialty Plastics)

The first commercially available polysulfone (PSU) was Udel, which was introduced by Union Carbide in 1965 (see also Section 6.12.2). Udel polysulfone [*25135-51-7*] is produced by reacting bisphenol A and 4,4′-dichlorodiphenyl sulfone. The material is amorphous, with a glass transition temperature of 190 °C, and can be converted into film either by extrusion or by solution casting.

Polysulfone films are available in thicknesses ranging from 25 to 1000 µm. They are highly transparent, possess high heat and dimensional stabilities, and can be thermoformed. Their electrical properties are comparable to those of biaxially oriented polyester films. Polysulfone films are suitable for long-term use at temperatures up

to 150 °C, making them superior in this respect to polyester films. Polysulfone films are also stable to alkali, acid, oils, and detergents, although they are attacked by ketones and chlorinated or aromatic hydrocarbons. The properties of Udel PSU film are listed in Table 5.

Principal applications are in packaging, the electrical industry, adhesive tape manufacture, and display technology [37].

Trade Names. Sumilite FS 1200 (Sumitomo Bakelite, Japan); Europlex-Folie (Röhm, Federal Republic of Germany).

6.11. Polyimide (PI) (→ Polyimides)

The most important polyimide [*25036-53-7*] (PI) for film production is derived from pyromellitic acid and 4,4′-diaminodiphenyl ether [38]. Films made from this material do not melt, and they have the highest thermal stability of any synthetic film. They are suitable for long-term applications at temperatures up to 240 °C and short exposure to peak temperatures of up to 400 °C. For properties, see Table 5.

Polyimide films are prepared by dissolving the appropriate monomers in a suitable solvent (e.g., *N,N*-dimethylacetamide), in which they react to form a soluble intermediate (polyamic acid). The film is cast from this solution and is subsequently converted into the insoluble polyimide by intramolecular condensation at 300 °C.

The combination of high thermal stability and flame resistance, along with stability to radiation and favorable electrical properties, makes this film attractive for applications in the aerospace industry (e.g., as an electrical insulator), and the manufacture of electronic components [39]. Commercial grades range in thickness from 7.5 to 125 µm.

Worldwide capacity in 1986 was 1400 t/a with an expected annual growth rate of 10 %.

Trade Names. Kapton (Du Pont, United States; Toray/Du Pont, Japan); Upilex (Ube Industries, Japan); Novax (Mitsubishi Chemical, Japan).

6.12. Other Films

6.12.1. Polyetherimide (PEI)

The backbone of polyetherimides (PEI) contains both ether and amide linkages. The PEI used for film production was first marketed by General Electric in 1982 under the trade name Ultem and is an amorphous thermoplastic polymer with the structure:

[*61128-24-3*]

Poly(etherimide) film is prepared by the chill roll process at an extrusion temperature of 350 °C and is available with a thickness of 75 – 500 µm.

This film is especially suited for electrical applications due to its favorable mechanical and electrical properties. The maximum temperature for long-term use is 170 °C; thus, thermal stability is substantially less than that of conventional polyimides. Nonetheless, stability is adequate for many purposes and significantly higher than that of polyester film [37]. The film is used mainly for electrical insulation. For properties, see Table 5.

Trade Names. Ultem Films (Westlake, Dixon, United States); Sumilite FS-1400 (Sumitomo Bakelite, Japan); Europlex PEI (Röhm, Federal Republic of Germany).

6.12.2. Polyethersulfone (PES) (→ Specialty Plastics)

The poly(ethersulfone) (PES) used in film manufacture is an amorphous, thermoplastic material manufactured by ICI under the trade name Victrex. It consists of aromatic rings linked alternately by ether and sulfone groups:

[*25667-42-9*]

Poly(ethersulfone) film is normally manufactured by the chill roll process, although it can also be cast from solution. Thicknesses vary from 25 to 300 µm. Its range of applications is determined by its electrical and optical properties combined with its thermostability and flame resistant behavior [37], [40], [41].

Poly(ethersulfone) films are used in electrical insulation, interior aircraft fittings, and liquid crystal displays.
Trade Names. Stabar (ICI, United Kingdom); Victrex PES-5200 G (Westlake, United States); Talpa 1000 (Mitsui Toatsu, Japan); Sumilite FS 1300 (Sumitomo Bakelite, Japan); Europlex-Folie (Röhm, Federal Republic of Germany).

6.12.3. Poly(ether ketone) (PEK)

Poly(ether ketones) [*2738–27–4*] can be extruded into either fibers or films in the temperature range 350–420 °C.

Films made from PEK display high thermal stability (up to 240 °C), solvent and chemical resistance, good dimensional stability, flame resistance, and stability to both radiation and hydrolysis. Properties are listed in Table 5. Since PEK film also possesses favorable electrical properties and is a low-density material, it is used in the aerospace industry.

Both crystalline and amorphous unoriented films are commercially available in thicknesses from 75 to 250 µm [37], [41], [42]. Oriented films are still being developed.
Trade Names. Stabar K and XK (ICI, United Kingdom); Sumilite FS 1100 (Sumitomo Bakelite, Japan); Talpa 2000 (Mitsui Toatsu, Japan).

6.12.4. Poly(Phenylene Sulfide) (PPS)
(→ Specialty Plastics)

Poly(phenylene sulfide) [*9016-75-5*] (PPS) was marketed as early as 1973 by the Phillips Petroleum Company under the trade name Ryton. However, it was not until 1985 that Phillips, in collaboration with Toray, succeeded in producing the material in film quality.

Poly(phenylene sulfide) is a partially crystalline polymer prepared from sodium sulfide and 1,4-dichlorobenzene. Poly(phenylene sulfide) film is manufactured by extrusion at 300 °C and is similar to PETP film in that it can be biaxially oriented and heat-set. Properties of PPS film are given in Table 5. Thicknesses are in the range 2 – 125 µm.

Poly(phenylene sulfide) film combines favorable electrical characteristics with high thermal stability [43]. Thus, it is mainly used in the electrical industry, although it also has potential as a magnetic storage medium.
Trade Names. Torelina (Toray, Japan).

6.13. Composite Films [44]

The most important production methods for composite films are adhesive lamination, extrusion coating (see Section 2.4.3), and, more recently, the simultaneous extrusion (coextrusion) of several raw materials (see Section 2.4.2). The latter approach is unique in that it can produce very thin multilayer films (ca. 12 µm) that still display combined properties.

The incorporation of PETP, BOPP, PA, and PVC into composite films permits optimization of ultimate strength, elongation at break, and puncture resistance.

Composite films are especially important as packaging materials, particularly for bulk materials regardless of their state, i.e., gases, liquids, and solids.

Composite films that contain polyethylene can be welded by either heat impulse or thermal sealing methods. Thin polyethylene layers (ca. 30 µm) may suffice for packaging lightweight goods, provided that no need exists for evacuation or a controlled atmosphere. Moderately thick layers (≥ ca. 40 µm) are required for vacuum and inert atmosphere packings. Thicker PE film (≥ ca. 60 µm) is employed if the material to be packaged is a liquid or a paste.

The combination of plastic films with aluminum foil produces semirigid composites with exceptionally low permeability to gases, water vapor, and odors. Special heat-sealable, polyolefin-based layers result in composite films that can be separated by peeling. Composite films incorporating ionomers are especially suitable for packaging oily materials.

7. Summary of Uses [2], [10], [26], [27]

The most important uses of individual films have been described in Chapter 6 and are summarized in Table 6. They can be divided into three main categories: packaging, electrical insulation, and use as bases for other active materials.

Table 6. Uses of films

Application	Film material*

Packaging. Packaging is the most important application of films; virtually every type of film finds some application in the packaging field. Plain and printed films are commonly used in packaging a wide range of foods and nonfood articles. Legal requirements for food packaging are described in [25] (see also → Foods, 4. Food Packaging, Chap. 8.4.).

Tubular film prepared either directly by blowing or by the subsequent sealing of flat film is used for the manufacture of a wide variety of bags, sacks, and blister or cushion packs. Thicker films are thermoformed into bottles, containers, cups, trays, and bowls. Shrinkable film is employed in palette packaging. Film is also the basis of skin packings, packing tapes, and even tear-off bands. Decorative iridescent packaging films are available which consist of layers of two or more different polymers with different refractive indices. The iridescent color is produced by light interference [45]. Special characteristics such as impermeability to gases and water vapor can be obtained by applying coatings or using laminated structures.

Electrical Insulation. Films with a high dielectric constant and a low dielectric loss factor are particularly useful in a.c. and d.c. capacitors. Such films may be as thin as 1.0 μm. The films themselves are dielectrics, but they can be converted to electrodes either by vacuum metallizing or by combining them with aluminum foil. Polyester and PI films, either alone or in combination with paper or synthetic nonwoven materials serve as insulating material in electrical equipment. Polymer films are also employed in cable sheathing; thin strips of film are often used as electrical insulation or labels; they also create plasticizer barriers, provide thermal and mechanical insulation, and, in combination with metallic film, confer protection against static charging. Polyester (PETP), PC, and PI films are used in the production of flexible printed circuits because of their exceptional dimensional and thermal stability. Film switches represent a new area of application, especially for PETP film.

Base Films for Functional Coatings. Polyester film in particular has acquired major significance as a base material for magnetic coatings. Special polyester films combining extra strength with defined surface roughness have been developed for this purpose. Magnetic tapes based on these films are marketed internationally for audio cassette players, video recorders, computers, and other commercial and industrial recording equipment (→ Information Storage Materials).

Films with a high dimensional stability (e.g. PETP) are used as substrates for drafting and photocopying. Films are also used in the printing industry as carriers for transferring color to paper or plastics (stamping foil). Film coated with deformable materials are used as embossing films. Iridescent films and films coated with firmly bonded layers of metal and/or lacquers are frequently used for decorative or display purposes. Films are also the basis for most adhesive tapes. The introduction of a wide range of film-based typewriter ribbons are another application.

Miscellaneous. The furniture industry employs films as veneers for the surface treatment of sheet materials. Thicker films (sheets) are thermoformed into ceiling and wall panels, as well as decorative fixtures and reproductions.

The use of films in heat mirrors and solar collectors (→ Solar Technology) is a more recent development. Heat mirrors employ coated films (mostly PETP) that transmit visible light and reflect infrared light. In solar collectors, solar energy is absorbed and passed to a flowing heat-transfer medium (e.g., water). Solar collectors may be constructed from UV-stable film.

Film is frequently used as a protective covering for equipment and materials. Many modern greenhouses are constructed almost entirely from transparent film material. The building industry generally makes frequent use of films on account of their waterproofing properties. Small amounts of films are used for rainwear and clothing.

8. Environmental Aspects

Most of the scrap rolls and waste generated in film production as a result of edge trimming and manufacturing problems is collected and recycled. Special facilities are required for shredding the film and compressing it into granules suitable for reprocessing.

Film constitutes 1 – 2 % of normal household waste. Separate collection and recycling of waste film is in theory possible, but is expensive and requires considerable organization. All films can be regarded as environmentally harmless, provided that they are disposed of properly. Combustion of film waste presents no particular technological problems. Even PVC film can be safely incinerated, although public controversy suggests otherwise; modern combustion facilities are capable of trapping any hydrogen chloride vapor that is formed.

Films can create litter problems; a number of film additives and other chemical modifications have been proposed for accelerating the rate at which films undergo photooxidative decomposition. However, apart from one exception these suggestions have not been implemented, primarily because the required precision in formulation for a given application is difficult to achieve. In addition they conflict with the present ideas of litter prevention. The sole exception is the *mulch film* employed in agriculture for stimulating seed germination and growth; this product is designed to have a lifetime of only one growing season.

1. Introduction

Fire extinguishing agents include water, water plus additives, "dry chemicals," inerting gases, and halogenated compounds, each specifically suited for certain types of fires. Water is the oldest means of extinguishing fire, and chemicals are used as additives to enhance its characteristics for fire control. Dry chemical agents are mixtures of powders applied from portable devices or from fixed systems. Inerting systems using nitrogen, carbon dioxide, or flue gas have long been used in fire control, especially in marine applications. Use of halogenated agents, with superior flame extinguishing properties, was increasing worldwide in the 1980s.

The type of extinguishing agent depends on the class of the combustible material. Various systems are used to classify combustibles and to determine the most effective type of extinguishing agent [1].

Table 1 illustrates three major systems for fire classification. Some of these systems categorize fire control agents according to the class or classes of fire for which they are most effective and applicable. Although separation into classes of fire is often difficult in actual fire situations, the classification systems allow an accurate description of a fire situation and identify some of the hazards associated with the fire-fighting activity.

2. Water as an Extinguishing Agent

Water is the single most useful and efficient material for controlling and halting combustion and fire. Because water is generally plentiful, its use is relatively inexpensive and effective. The efficiency of water for extinguishing fire is primarily due to the change in physical state from liquid to vapor. The heat of vaporization, which is 2260 kJ/kg, removes heat from the combustion process. As an example of the heat removal capability of water, a typical fire-fighting nozzle applying water at 380 L/min (100 US gal/min) directed into a fire removes nearly 1000 MJ/min. In comparison with the complete combustion of 1 L of gasoline, which produces >36 MJ/kg, the extinguishing efficiency of water can be fully appreciated [2].

Additional advantages of water as an extinguishing agent include the following:

1) Has the ability to dissolve and wash away many products of combustion so that the seat of the fire may be reached
2) Can be easily pumped through hoses and pipes because of the small change in viscosity with temperature in the liquid phase between 1 and 99 °C
3) Expands to steam, which has ca. 1700 times the volume of the liquid; makes confined spaces inert by displacing air and oxygen, aiding in fire extinguishment
4) Has high surface tension (0.073 N/m), which enables water to be issued in a consolidated stream or in discrete water droplets from spraying devices or "fog" nozzles
5) Has a density high enough to provide a physical mass to a nozzle stream, which assists in physical penetration

Table 1. Classification of fire-extinguishing agents

Classification	United States	United Kingdom	Federal Republic of Germany
Class A fire	normal combustibles: wood, cloth, paper, rubber, and plastics	solid materials (organic matter): fire occurs with formation of glowing embers	*
Class B fire	flammable and combustible liquids, gases, and greases	liquids or liquefiable solids	*
Class C fire	energized electrical equipment that may be harmed by the extinguishing media	gases or liquefied gases from a liquid spill or a liquid or gas leak	*
Class D fire	combustible metals, such as magnesium, titanium, zirconium, sodium, or potassium	combustible metals	*
Electrical fire	see Class C	no separate classification; de-energize and use appropriate agent for class of fire remaining	see Class E
Class E	see Class C	see Electrical fire	extinguishing agent chosen for fire of surrounding material: foam should not be used; water should be used only in the form of a fog and at a safe distance (>5 m), depending on the voltage

* Identical to United Kingdom classification.

6) Has molecular stability; does not break down or dissociate appreciably at <1650 °C, which exceeds ordinary flame temperature

Although water is the most useful and efficient heat-removing agent for fire-fighting purposes, some physical properties restrict use under certain conditions, including the following:

1) When frozen, water cannot be transported or applied easily to a fire.
2) High surface tension restricts ability to penetrate and wet below the surface area of combustibles to extinguish deeply sourced fires.
3) Water readily runs off surfaces, leaving a coating too thin for heat removal or surface protection.
4) Transportation through hoses or pipes results in loss of pressure because of friction.
5) Density and immiscibility reduce effective control of hydrocarbon fires; water sinks below the fuel even when used in a fine spray.
6) Water vapor explosion may occur if spontaneous vaporization is possible, e.g., in the case of molten salts, bitumen, or other products with a temperature >120 °C.
7) Use of water to fight fires of lower molecular mass metals may be dangerous.

Chemicals that change water's characteristics by depressing freezing point, reducing surface tension, increasing viscosity, and modifying flow properties or water density have been developed and extend the capability of water as an extinguishing agent.

Inorganic freezing point depressants prevent water from crystallizing at low temperature. Calcium chloride [*10043-52-4*], used in 94 % pelleted grade, depresses the freezing point of water to as low as −40 °C; sodium chromate [*10034-82-9*] is added (0.5 wt % of the calcium chloride used) for corrosion protection. Other antifreeze materials, such as ethylene glycol [*107-21-1*], propylene glycol [*57-55-6*], and glycerol [*56-81-5*], are also used for cold-weather protection, primarily in automatic sprinkler systems. However, care must be taken to prevent contamination of public water supplies. The use of these materials in portable extinguishers is not recommended because residual antifreeze is flammable after the fire evaporates the water.

Wetting agents lower the surface tension of water from a normal level of 0.073 N/m to ca. 0.025 N/m, which allows water to penetrate solid materials and extinguish fires below the surface. Wetting agent solutions are most useful when used on tightly consolidated Class A fire hazard materials, such as straw, mattresses, or cotton bales, where the water, with a lower surface tension, reaches the deep-seated fire by capillary action more quickly and with better efficiency than water without a wetting agent.

Viscosity-enhancing materials or "thickeners" increase the viscosity of water so that it may be applied to nonhorizontal surfaces. Two principal types of water thickeners are used: those that produce an organic gel and those that give a slurry. Gels either coat the material that is burning or prevent the material from igniting. Bentonite [*1302-78-9*], a powdered mineral, yields a water slurry, as does ammonium phosphate [*7783-28-0*] or ammonium sulfate [*7783-20-2*]. Ammonium sulfate gives a thick slurry, which is used particularly in combating forest fires. These slurry-type mixtures retard flames because of their solids content and the capability of ammonium salts to halt flaming and glowing ignition.

Flow property modifiers reduce friction resulting from water flowing at high velocity in a hose. Water pumped at high velocity through the small-diameter hose that is commonly used for fire fighting loses pressure because of friction between the water and the hose walls and because of turbulent flow within the hose. Dilute solutions of poly(ethylene oxide) [*25322-68-3*] can yield nonturbulent water flow in a fire hose. Flow increases of 55 – 70 % can be achieved in a 3.8-cm fire hose when 0.017 vol % poly(ethylene oxide) is added. Nozzle pressure at the end of the hose is doubled when the flow modifier is used. An added benefit from the water stream modifer is the ability to use small and more manageable hose sizes without loss of nozzle pressure or flow volume.

Water density modification for fire-fighting purposes is achieved by adding air to water to form a semistable air foam that is lighter than most flammable and combustible liquids or to emulsify the top layer of a burning liquid to obtain a nonflammable floating emulsion of water and fuel. As do wetting agents, synthetic detergents lower the water's surface tension. Detergents are chosen for their emulsification action. When they are sprayed or directed into flammable or combustible fuels, detergents mix rapidly to produce a suspension of the fuel in the detergent solution. Emulsification lowers the fuel's vapor pressure, which reduces the vapor concentration to below the lower flammable limit in air; thus, the fuel no longer burns. Synthetic detergent emulsifying agents are used at a concentration of 0.5 – 2.0 vol % yielding a fuel – solution – air emulsion with a lower density than that of either water or fuel. Although the emulsion may be temporary, fires involving fuels with a high flash point require only a short interruption of combustion to halt reignition.

3. Fire-Fighting Foams

Fire-fighting foam is a mass of gas-filled bubbles formed from aqueous solutions of specially formulated, concentrated liquid foaming agents. The gas normally is air, but may be an inert gas.

Because the density of the resulting foam is so low, it floats on the surface of flammable and combustible liquids, producing an air-excluding, cooling, continuous layer of vapor-sealing, water-bearing materials that halts or prevents combustion [3]. Various methods and types of equipment are available to generate and apply foam.

Formulation. Fire-fighting foams are formulated in several ways for fire extinguishing action. Foams are produced by mixing an appropriate amount of foam concentrate with water and then aerating and agitating the solution to form the bubble structure.

Some foams are thick and viscous, forming a tough heat-resistant blanket over a burning liquid or on a vertical surface; others are thinner and spread more rapidly. Foams that produce a vapor-sealing film of surface-active water solution on a liquid surface are available. Some foams are used as large volumes of wet gas cells for filling cavities and inundating surfaces.

Foams are defined by their *expansion ratio*, which is the ratio of final foam volume to original solution volume before the air is added. Foams are arbitrarily subdivided into three ranges:

1) low-expansion foam: expansion up to 20 : 1
2) medium-expansion foam: expansion range from 20 : 1 to 100 : 1
3) high-expansion foam: expansion range from 200 : 1 to 1000 : 1

3.1. Limitations and Uses

Low-expansion foam develops a cooling, coherent blanket and is used primarily to extinguish burning flammable or combustible liquid fires, such as in spills or in storage tanks. Foam extinguishes fires progressively by first providing

a cover on the surface of the liquid, such as in a storage tank, to prevent vapor transmission and then by cooling hot surfaces adjacent to the burning liquid to prevent reignition. Foams are also able to diminish or halt the generation of flammable vapors from liquids or solids. Medium expansion foam is used primarily to control spill fires and to fill cavities where toxic or flammable vapors may collect.

Use of medium- or high-expansion foam that has air in the bubbles may be dangerous in a small room. If the vapor concentration in the room is higher than the explosive limit, the air from the foam may be enough to cause an explosion. Such accidents have occurred.

When attacked by heat and flame, foam breaks down and the water content vaporizes. Foam must be applied to a burning liquid surface in sufficient volume and rate to compensate for evaporation, with additional foam required to establish a residual layer over any exposed fuel. Foam is an unstable "air – water emulsion" that is easily dissipated by mechanical or physical forces, by some chemical vapors or fluids, and by incompatible extinguishing agents. Turbulent air or a violent uplift of combustion gases can also divert light foam from the burning area.

Foam solutions are conductive and are not recommended for use on electrical fires. If foam is used near electrical equipment, precautions should be taken to minimize chances of electrical shock.

3.2. Foam Concentrates

Some foam concentrates are available for specific applications, whereas others are more suitable for extinguishing fires in all types of flammable liquids, including water-soluble and foam-destructive liquids.

Protein Foaming Agents. Concentrates of these foaming agents consist of protein fragments derived from chemical digestion and hydrolysis of natural protein solids. The material gives elasticity, mechanical strength, and water retention capability to the resulting foams.

The concentrates also contain dissolved polyvalent metallic salts, which strengthen the bubbles when the foam is exposed to heat and flame. Organic solvents are added to the concentrates to improve foam formation and uniformity, as well as to control viscosity at lower temperature.

Protein-type concentrates are available for use with either fresh water or saltwater at 3 or 6 vol % concentrations. The resulting foam is dense, viscous, and highly stabile; its resistance to high heat and burnback is superior to that of other foaming agents. These foams cling to vertical surfaces and insulate them if the proportioning rate is increased or the water content reduced.

Fluoroprotein Foaming Agents. These agents contain an additional fluorinated, surface-active compound that provides a fuel-shedding property to the resulting foam. These foams are particularly effective for fire-fighting situations in which the foam becomes coated with fuel, such as when subsurface or base-injected foam is used for fires in storage tanks or for foam streams applied from hose nozzles where falling foam may plunge into the burning fuel pool. In addition, the resulting foam has a greater compatibility with dry chemical agents than that of protein foam. As with protein foam, the concentrate is used with either fresh water or saltwater at concentrations of 3 or 6 vol %.

Aqueous Film-Forming Foaming Agents (AFFF). The AFFF agents are synthetic compounds that form air foams similar to those produced by the protein-based materials. In addition, these foaming agents are capable of forming water solution films on the surface of flammable liquids from which the term aqueous film-forming foam is derived. The AFFF concentrates are used at either 3 or 6 vol % with fresh water or seawater.

The air foams generated from AFFF solutions possess low viscosity, have fast spreading and leveling characteristics, and, like other foams, act as surface barriers to exclude air and halt fuel vaporization. The unique feature of these foams is the continuous aqueous layer that forms under the foam. This floating film on the hydrocarbon fuel surface helps suppress combustible vapors and cools the fuel substrate. The film is capable of spreading over fuel surfaces not fully covered by foam; it is self-healing when mechanically disrupted and continues to spread as long as a reservoir of nearby foam remains. Hot surfaces can reduce foam effectiveness as can aromatic

hydrocarbons. The insulating effect in protecting flammable or combustible liquids against radiant heat is lower with these foams compared to protein foams.

Concentrates of AFFF agents contain fluorinated, long-chain synthetic hydrocarbons with particular surface-active properties. Various water-soluble, high-molecular mass, synthetic polymers are added to aid in strengthening the bubble wall and in retarding breakdown.

As used, these foams are nontoxic and biodegradable in diluted form. Because of the low surface tension of solutions draining from AFFF, the foams may be useful under mixed class fire situations (Class A and B), where deep penetration of water is needed to extinguish deeply sourced fires in Class A materials. The AFFF concentrates must not be mixed with other types of foam concentrates; however, the foam itself does not break down other types of foams in fire-fighting operations. The AFFF agents are compatible with dry chemical fire-fighting compounds.

Synthetic Hydrocarbon Surfactant Foaming Agents. These hydrocarbons are synthetically produced surface-active compounds that foam copiously in water solution; however, their use for fire fighting requires some care. These compounds are also used at concentrations of 3 or 6 vol % in water.

Fire-fighting characteristics depend on the volume of foam layer on the burning surface that restricts air and controls combustible vapor production. In addition, a minor cooling effect comes from the water contained in the foam, which is a function of the rapid drain time of the water from the foam mass. This drain time leaves a bubble mass that is highly vulnerable to heat or mechanical disruption. A rate of application higher than that used with ordinary fire-fighting foams is required to gain control and extinguishment. The foams from these agents are sometimes destructive to normal fire-fighting foams.

Alcohol-Type Foaming Agents. Alcohol-compatible agents are used on fires involving fuels that are water soluble, water miscible, or are polar solvents. They can also be applied to normal flammable liquids, but are most effective when used on fires in alcohols, enamel and lacquer thinners, methyl ethyl ketone, acetone, and acrylonitrile. Relatively small amounts of these substances rapidly deteriorate ordinary fire-fighting foams.

Proprietary compositions of several alcohol-type concentrates, based on concentrate bases of protein, fluoroprotein, or AFFF foams, have been developed. The most common are usually described as polymeric alcohol-resistant AFFF concentrates, which produce foams suitable for application to either flammable hydrocarbons or water-miscible liquids. These substances exhibit AFFF characteristics when used on hydrocarbons and produce a floating gel-like mass for foam buildup on water-miscible fuels.

High-Expansion Foaming Agents. High-expansion foaming agents are used to control and extinguish Class A and Class B fires and are particularly well suited for flooding confined spaces. Applications are generally indoor because out-door use is limited by the weather.

Liquid concentrates for producing high-expansion foam consist of a synthetic hydrocarbon surfactant that will foam copiously with a small input of turbulent action. Normally 1 – 2 vol % of concentrate in water is used. The air supply for foam generation should be outside the fire area because combustion products have an adverse effect on the resulting foam volume and stability. Tests have shown that expansion ratios of ca. 500 : 1 are the most effective for controlling fires and reducing vaporization from liquefied natural gas (LNG) spills. As water drains from the foam, a thin ice layer is formed. This ice layer floats on the LNG and supports the high-expansion foam blanket, retarding vapor generation and possibly building a shield to protect the LNG surface from radiated heat.

Chemical Foaming Agents and Powders. These materials have become obsolete because of the superior economics and ease of handling of liquid foam-forming concentrates. Chemical foam is formed by the aqueous reaction of aluminum sulfate [*10043-01-3*] and sodium hydrogen carbonate [*144-55-8*]; the foam also contains proteinaceous stabilizers. The carbon dioxide [*124-38-9*] gas that results is trapped in the foam.

3.3. Guidelines for Using Fire-Fighting Foams

Foams are effective for fire control if the following general rules are applied:

1) Foam application should be gentle because agitated application increases the time to extinguish the fire and the amount of foam concentrate used.
2) Successful use of foam depends on the rate of application. Rates are expressed in terms of the amount of foam solution (by volume) reaching the total area of fuel surface each minute. Thus, an expansion rate of 1 : 8 with an application rate of 4.1 $L\,min^{-1}\,m^{-2}$ provides 32.8 $L\,min^{-1}\,m^{-2}$ of finished foam. Increasing foam application rate over the minimum generally reduces time to extinguish the fire. If application rates fall below the minimum, extinguishment is improbable. Application rates are determined by vendors or approval laboratories.
3) Foams are more stable when generated with water at an ambient temperature of 2 – 27 °C; either fresh water or seawater can be used. Foam contaminants, such as detergents, oil residues, or certain corrosion inhibitors, may adversely affect foam quality.
4) The location of foam-making device air inlets is important because combustion products can adversely affect foam quality.
5) The pressure of water in foam-making devices affects foam quality; high or low limits should not be exceeded.
6) Some fire-fighting chemicals, such as vaporizing liquid extinguishing agents and dry chemicals, can adversely reduce the effectiveness of foam.

4. Dry Chemical Extinguishing Agents

Dry chemical agents, which are mixtures of powdered chemical compounds of varying composition, have the most efficient flame-halting capability. The compounds are stored in moisture-proof containers and are pneumatically blown into a fire by a pressurized gas discharge that conveys the solid powder into the combustion zone. Dry chemicals, known as dry powders in the United Kingdom, do not extinguish fire by cooling, smothering, or emitting an inert gas, but instead provide instantaneous and momentary flame extinction [1, p. 199], [4].

Extinguishers for applying dry chemicals onto fires evolved from hand-held tubes of sodium hydrogen carbonate to a variety of portable and fixed fire extinguishing systems using dry chemical pressurized-gas propellant. Particle size range of the mixture is 5 – 75 µm, with most in the range of 20 – 25 µm.

In 1959 the U.S. Navy developed the *potassium hydrogen carbonate* [*298-14-6*] formula for dry chemicals. This material has twice the flame-quenching capacity per unit mass as the sodium compound. The material is called Purple K because it exhibits a purple flame when it encounters a flame. Purple K is compatible with AFFF when applied in twined nozzle systems and provides rapid control of burning spilled flammable liquids, such as during an airplane crash.

Ammonium dihydrogen phosphate [*7722-76-1*]has an extinguishing action on flammable liquid fires similar to that of sodium hydrogen carbonate. However, ammonium dihydrogen phosphate also decomposes when heated to yield a glassy coating of metaphosphoric acid [*37267-86-0*], HPO_3, which may halt further combustion of Class A fuels such as wood. This extinguishing agent is useful for fires in either Class A or Class B fuels. Electrical fires, Class C, can also be extinguished by dry chemicals because the powder is not electrically conductive. Extinguishers containing this agent are "multipurpose" because they can be used on Class A, B, or C fires.

A potassium-based dry chemical consisting of *potassium chloride* [*7447-40-7*] or Super K has been developed for fire fighting. This agent exhibits a flame-extinction efficiency that is slightly less than that of potassium hydrogen carbonate.

Monnex, an extinguishing agent developed by ICI (United Kingdom), consists of the addition product of urea and potassium hydrogen carbonate and is unique in its mode of reaction. Urea [*57-13-6*] can form adducts, or inclusion complexes, under certain processing conditions. These complexes are crystalline mixtures in which the molecules of one of the components

are contained within the crystal lattice framework of the other compound; the original components separate when the mixture is heated. In Monnex, urea is contained in the potassium hydrogen carbonate lattice.

A finely powdered dry chemical is a more efficient flame-quenching agent than the same powder with a coarser particle-size distribution. Fine powders cannot be projected great distances, however, which makes them impractical for fire extinguishing purposes. The urea–potassium hydrogen carbonate particles are of normal and customary size distribution and can be projected efficiently through a nozzle under gas pressure. However, when heated, the crystals shatter, yielding fine particles and resulting in more efficient flame-quenching than is normally obtained.

5. Inerting Gas Extinguishing Agents

Inerting gases extinguish or prevent fire by partial exclusion of oxygen from contact with the combustible material. Inerting gases include gases that do not react with combustible materials and can dilute oxygen or air atmospheres to the point where oxidation (or combustion) either cannot start or cannot continue. Helium [*7440-59-7*], argon [*7440-37-7*], krypton [*7439-90-9*], nitrogen [*7727-37-9*], carbon dioxide [*124-38-9*], and sometimes water vapor are used to produce inert atmospheres. Flue gases or products of combustion gases, such as those from oil burners, are also inerting gases because of their high carbon dioxide and nitrogen content and low (ca. 5 %) oxygen content. Applications for flue gas inerting include marine petroleum tankers where flue gases are used for storage tank inerting. Carbon dioxide and nitrogen are the principal inerting gases currently used.

Carbon dioxide gas has long been used as an inerting agent for fire extinguishment and prevention [5]. Carbon dioxide is noncombustible and does not react with most substances. The gas provides its own pressure for discharge from storage containers used for fire-protection applications. As a gas or as a finely divided solid (dry ice), carbon dioxide does not conduct electricity and is ideal for use on energized electrical equipment.

Carbon dioxide is the only inerting gas of which large volumes can be liquefied and maintained in that state in a small container volume at ordinary temperature and at moderate pressure. Carbon dioxide vapor is more dense than air, so the gas sinks to the base of the flames, replacing air and oxygen and maintaining a flame-smothering atmosphere. Carbon dioxide extinguishes flammable and combustible liquid and gas fires at concentrations of ca. 30 – 38 vol % carbon dioxide; however, a higher concentration may be necessary to extinguish certain gases that have wide flammable limits. Specific requirements of the vendor, regulatory standards, or fire codes should be consulted for particular applications.

Reignition is possible once the carbon dioxide dissipates and air (oxygen) contacts the combustible material before the material has cooled below its ignition temperature or fire point. Deep seated fires may continue in Class A materials after flame control has been achieved with carbon dioxide application. The gas diffuses slowly through materials that are difficult to penetrate. Therefore, cooling of these materials is necessary and is normally accomplished by maintaining an atmosphere of ca. 38 % carbon dioxide for a period of time.

Two principal types of *storage units* are used to contain carbon dioxide for fire-protection applications. In the high-pressure method, the liquid and gas phase are at equilibrium in a steel container at ca. 6 MPa pressure. The familiar portable CO_2 extinguisher is an example of the high-pressure container. The low-pressure storage unit is maintained at ca. 2 MPa and kept at −18 °C by a refrigeration unit. This method allows large amounts of CO_2, mostly in the liquid state, to be stored in light, steel-walled containers. Larger systems generally incorporate fire detectors and automatic or remote manual activation devices. An alarm, sounding 15 – 20 s before gas release, is required for confined spaces to avoid asphyxiation of any personnel that may be present.

Nitrogen is used as an oxygen diluent to halt combustion and produce an inert atmosphere [1, p. 191], [6]. However, nitrogen is not easily condensed. The gas must be stored at high pressure

(ca. 14 MPa) in heavy cylinders, which limits its application as a fire extinguishing material or inerting gas. In addition, because it is slightly lighter than air, nitrogen is difficult to direct or maintain near the base of flames or seat of the fire, where it is needed to be the most effective. Applications in liquid form have been attempted, but the extensive quantities that are needed are not currently practical.

Water vapor can be used, in special cases, as an extinguishing agent or inerting gas. However, high-pressure steam can generate static electricity, which can ignite flammable vapors, unless special precautions are taken.

6. Halogenated Extinguishing Agents

Although elemental halogens are vigorous oxidizing agents when reacted with metallic and nonmetallic elements with one or more atoms of oxygen, the resulting ionic halogens chemically combine with and reduce many compounds. Reaction of elemental halogens with highly oxidizable hydrocarbons, such as methane [*74-82-8*], ethane [*74-84-0*], or propane [*74-98-6*], using special high-temperature methods in the absence of oxygen, yields a gaseous or liquid organic compound that is capable of decomposition and is an efficient fire-extinguishing agent. Early halogenated extinguishing agents included carbon tetrachloride [*56-23-5*] and methyl bromide [*74-83-9*].

Halons. In 1946 it became obvious that of all of the halogenated compounds, the lower aliphatic hydrocarbons substituted with bromine resulted in powerful extinguishing agents. However, the materials were toxic. The fluorine bond to carbon was known to be very stable, and if a compound containing some new ratio of fluorine : bromine : carbon could be synthesized, perhaps the result would be less toxic. This theory led to the development of the halogenated fire extinguishing agents known as Halons [1, p. 192].

Nomenclature for the Halons has been simplified. Integers are used to represent the various constituents in the material: the first digit represents the number of carbon atoms in the compound molecule; the number of fluorine atoms are indicated by the second digit; chlorine atoms are represented by the third digit; the fourth digit indicates the number of bromine atoms; and the fifth indicates the number of iodine atoms, if any. Hydrogen atoms are not numbered.

Some common halogenated extinguishing agents are listed in Table 2. Most countries allow use of Halon 1211 and 1301 for fire control; Halon 2402, which is highly toxic, has limited applications where humans are not present, e.g., for fuel tank or engine compartment inerting [7].

Halons are effective flame extinguishing agents because their density causes flames to sink and stay in the region of the base of the flames. Knowledge is limited about combustion kinetics and the influence of the actions and reactions of halogenated material. Evidence has shown that Halon agents remove the active chemical species involved in the chain reactions of flame propagation. In fire situations, Halons decompose at flame temperature and the resulting products have an affinity for the highly active free radicals ($\cdot$O, $\cdot$H, and $\cdot$OH) produced by burning fuels, subsequently removing them from further flame propagation. Halogenated agent efficiency occurs because of the following reactions:

1) Capture of active atomic hydrogen by halogen, removing hydrogen from further heat-producing reactions 2) Reaction of active free-radical hydroxyl groups from oxidation of fuels, followed by a halogen hydride reaction that results in water
2) Regeneration of active atomic halogen by the preceding reaction so that the processes of capture and removal of atomic and free-radical groups may be repeated

The flame-extinguishing performance of Halon 1301 is slightly superior to that of Halon 1211. In general, ca. 5 vol % of Halon 1301 extinguishes fires in most hydrocarbon fuels, compared with, e.g., 6 vol % of Halon 1211. Individual fuels should be tested or reference made to standard tables to predict the actual extinguishing concentration. An 8 – 9 vol % concentration is required to prevent flame propagation in combustible mixtures of ordinary fuels in air. Halon 1301 is ca. 2.5 times more effective than carbon dioxide.

Solid combustibles can sometimes be extinguished by using Halons; however, soaking time

Table 2. Halogenated extinguishing agents

Chemical name	CAS registry number	Trade name	Molecular formula
Bromomethane	[*74-83-9*]	Halon 1001	CH_3Br
Bromochlorodifluoromethane	[*74-97-5*]	Halon 1211	$CBrClF_2$
Bromotrifluoromethane	[*75-63-8*]	Halon 1301	CF_3Br
1,2-Dibromo-1,1,2,2-tetrafluoroethane	[*124-73-2*]	Halon 2402	$C_2F_4Br_2$

is required to allow the Halon to reach the seat of the fire in a mass of material. Soaking time varies with the solid combustible material composition and geometry.

Toxicology and Occupational Health. When Halons are used in occupied areas, toxicity, characterized by anesthetic or narcotic effects, must be considered. High Halon concentration can lead to dizziness, impaired coordination, and reduced mental acuity. At high concentration, prolonged exposure can result in unconsciousness or even death.

Halon 1301 is the least toxic and, for most applications, can be discharged into occupied spaces. Its TLV-TWA values and MAK are 1000 ppm and 6100 mg/m^3, respectively [8], [9]. System designs exceeding 7 vol % concentration have induced light-headedness and have reduced dexterity. Above 10 vol % toxic effects are considered potentially serious and these levels should be avoided. Halon 1211 has a lower threshold limit than Halon 1301 (TLVs and MAKs have not been established), and the effects at concentrations required for fire extinguishment are comparable to those of carbon dioxide.

In general, application from portable extinguishers in typical rooms is considered safe, but fixed systems should be restricted to unoccupied areas. Concentrations up to 4 vol % have been shown to be tolerable for a 1-min maximum exposure, which compares with the same exposure time for a 10 vol % concentration of Halon 1301.

7. Extinguishing Agents for Combustible Metal Fires

Class D combustible metal fires are an important consideration when materials that burn in air, such as elemental metals and their alloys, are being used. Many of these metals require extensive heat exposure before reaching ignition temperature, whereas others may ignite spontaneously.

Metals burn at extremely high temperature and are highly reactive. No extinguishing agent is known that will halt the oxidation reactions of burning metals. Dry sand, cement, and special powders are possible materials. Combustible metal fires can be extinguished by removing the metal's contact with air or oxygen, by smothering, by inerting, or by cooling the surrounding area to lower the temperature of the mass below its ignition point [10].

One proprietary mixture consists of graphite and foundry coke, carefully sized to facilitate easy handling, packing, and application to the burning metal surface by scoop or shovel. Graphite is difficult to ignite and is a good heat conductor; i.e., it absorbs heat and radiates it from the burning area. An organic phosphate added to the mixture decomposes to yield a noncombustible smoke that penetrates the spaces between graphite particles to exclude oxygen. The mixture is a reducing agent and is moderately effective for all metal fires.

Another proprietary mixture consists largely of carefully sized sodium chloride [*7647-14-5*] with tricalcium phosphate [*7758-87-4*] powder, and zinc stearate [*557-05-1*] added to facilitate discharge from a pressurized extinguisher through a delivery nozzle. A small amount of powdered thermoplastic material is added to the mixture to melt and hold the sodium chloride particles together for efficient cooling and smothering of the burning metal. This material is suitable for all metal fires. A powder specially formulated for sodium fires contains sodium carbonate [*497-19-8*] instead of sodium chloride [1, p. 205].

Inert gas blanketing of burning metals, e.g., with argon, helium, and neon [*7440-01-9*], is an effective extinguishing method where feasible.

Ternary eutectic chloride powder contains potassium chloride [*7447-40-7*], sodium chloride, and barium chloride [*10361-37-2*]. This mixture, when exposed to burning metals, melts and can cover the burning surface, thus excluding oxygen. Water, applied judiciously from a safe distance, can be used for burning magnesium or titanium. Water dissociates to hydrogen and oxygen at the burning metal surface, thus it may increase the burning rate. Water is not safe to use on burning sodium and other alkali metals.

1. Introduction

*Flame retardation*is a process by which the normal degradation or combustion processes of polymers have been altered by the addition of certain chemicals. The polymers exhibit resistance to decomposition by thermal stress when measured by standard tests. The degree of resistance to flammability is usually defined by a numerical value of the test as being more resistant to flame or fire than the unmodified polymer. Results of these tests should not be used exclusively to predict performance in an actual fire, although they are a guide in selecting materials. *Flame-retarded materials*, can be formulated to be more resistant to ignition than non-flame-retarded materials, or to have slower rates of flame spread in a major fire that is initiated by some other source; however, the flame-retarded article will ultimately burn.

2. Mechanism

A basic understanding of the different theories by which flame retardants function is essential for identifying and selecting the optimum material for any given situation. Many alternative materials can be used, and the cost performance often dictates the choice. Flame retardants function by their interaction or interference with one of the three required components of a fire:

1) a combustible substance or fuel
2) heat, supplied either externally or from the combustion process itself
3) an oxidizing gas, primarily oxygen.

2.1. Dilution

Reducing the total quantity of combustible matter improves overall flame retardation. For example, adding fillers, such as clays, to polymer systems (often 50 – 200 parts by weight per 100 parts of polymer) reduces flammability. However, in some cases, such as glass fiber reinforced composites, the glass fiber stiffens the polymer. On exposure to heat or a flame, the glass may prevent the polymer from melting away from the flame; thus, the material burns. In addition, the glass can act as a heat sink so that less energy input is required to ignite the polymer on a second exposure to heat.

2.2. Generation of Noncombustible Gas [1]

Some materials decompose when heated, generating noncombustible gases. These gases lower the oxygen concentration at the front of the flame and often result in flame snuffing because of lack of oxygen. This result is transitory because once the material decomposes the residual matter acts

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a11_123

as an incombustible diluent of the polymer matrix. An example of this type of flame retardant is *calcium carbonate* [*471-34-1*] which decomposes at 825 °C to generate the solid, calcium oxide, and the gas, carbon dioxide; these products do not support combustion. The use of calcium carbonate with brominated flame retardants is not recommended, however. Calcium carbonate and its more alkaline decomposition product, calcium oxide, absorb hydrogen bromide that is liberated from the brominated flame retardants to form inactive species, such as calcium bromide.

Some materials decompose to produce water vapor as the noncombustible gas. Heat is absorbed because of decomposition as well as vaporization of liquid water. *Aluminum oxide trihydrate* [*21645-51-2*], ($Al_2O_3 \cdot 3H_2O$) begins to decompose at 230 °C with the release of 34.5 wt % of its original mass as water vapor. *Magnesium hydroxide* [*1309-42-8*], or hydrated magnesium oxide, begins to decompose at 340 °C with the release of 31 wt % of the original mass as water. For processing polymers at elevated temperature, the higher decomposition temperature of magnesium hydroxide makes it preferable to hydrated alumina [1]. Typically, 50 – 100 parts by weight of these compounds are required per 100 parts of polymer to achieve flame retardation.

Azo compounds are used in forming foam polymer systems. These materials liberate nitrogen. Although effective in producing foams, their cost effectiveness compared to that of other compositions has eliminated their use as flame retardants.

2.3. Gas-Phase, Free-Radical Inhibition

[2], [3]

Combustion of hydrocarbons creates highly active fragments in the solid or condensed phase. These fragments vaporize, react with oxygen, and form free radicals. Free-radical formation is highly exothermic, resulting in volatilization of additional active fragments from the condensed phase. The process continues unless free-radical formation is interrupted and stable species are produced. Some of the reactions that may occur are as follows [2]:

$HO\cdot + CO \longrightarrow CO_2 + H\cdot$	Highly exothermic
$H\cdot + O_2 \longrightarrow HO\cdot + O\cdot$	Chain branching
$O\cdot + HBr \longrightarrow HO\cdot + Br\cdot$	Chain transfer
$HO\cdot + HBr \longrightarrow H_2O + Br\cdot$	Chain termination

The HBr from decomposing *brominated compounds* is very effective in deactivating free radicals in the vapor phase. The formation of new radicals is also reduced as less heat is generated, and the entire combustion process is slowed.

Chlorinated compounds function in the same manner. In practice, often twice as much chlorine-containing compound is required as bromine-containing compound. The difference approaches the atomic mass ratio for the two halogens, i.e., 79.90 : 35.45 = 2.25.

Compounds containing *iodine* are known, but are of limited use as flame retardants because of their poor thermal stability. The dark color of many organoiodine compounds is also a negative factor.

Compounds containing *fluorine* generally exist as functional polymers instead of as materials added to other polymeric systems to provide flame retardation. These polymers are very stable and decompose only at high temperature. Hydrofluoric acid, when finally liberated, is an effective free-radical deactivator.

Antimony oxide acts as a synergist with halogens, particularly chlorine and bromine [3]. It is almost totally ineffective if used without halogen. The trioxide [*1309-64-4*] is the common material used, although the pentoxide is also available. The pentoxide [*1314-60-9*], as manufactured, generally has a much finer particle size and is more efficient per unit mass added than the trioxide. Semitranslucent thermosetting polyester laminates containing the pentoxide are also possible. Because some thermoplastic polyesters are sensitive to residual activity in all forms of antimony oxide, alkaline salts of antimony oxide are used in these critical cases.

Synergism may occur through a series of reactions; the basic reaction in the case of brominated flame retardants is:

$$Sb_2O_3 + 6\,HBr \rightleftarrows 2\,SbBr_3 + 3\,H_2O$$

Antimony tribromide forms a dense white smoke that snuffs the flame by excluding oxygen from the front of the flame. Water from normal combustion causes the equilibrium to shift

to the left, forming antimony oxide, which is then available to react with fresh HBr from decomposing brominated compounds.

Some applications cannot take advantage of the synergy between halogen and antimony oxide. For example, epoxy – glass fiber printed circuit boards contain high levels of bromine instead of combinations of bromine and antimony oxide. Trace quantities of antimony oxide poison chemical treatments used to etch the copper-foil printed circuits.

The effectiveness of halogen in inhibiting radical formation is often a function of the organic structure to which it is attached. In polypropylene, a cycloaliphatic bromine compound is more efficient at low levels than a more stable aromatic bromine compound. This is because of the relative decomposition characteristics of the bromine compound and the polymer. However, with rubber-modified, high-impact polystyrene, the more thermally stable aromatic compound is more efficient.

Typically, halogenated compounds used in applications of flame retardants contain either 40 – 70 wt % chlorine or 45 – 80 wt % bromine. From 20 to 40 parts of chlorinated compound or 5 – 30 parts of brominated compound would be used per 100 parts of polymer, depending on the flame retardant requirements. Antimony oxide use is typically 25 – 50 % that of the halogenated material.

Poly(vinyl chloride) has inherently good flame-retardant characteristics because of the high chlorine content. Antimony oxide (3 – 5 wt %) is often helpful in passing the more stringent flammability tests.

2.4. Solid-Phase Char Formation

Several different types of flame retardants form insulating or minimally combustible chars on polymer surfaces exposed to external heat sources. This char reduces volatilization of active fragments and absorbs and dissipates heat. The effectiveness of the flame retardant is specific for each polymer. For example, phosphorus-based flame retardants are effective in producing a minimally combustible char in phenylene oxide – ether polymers, but are essentially ineffective in styrenic polymers.

Phosphorus and Boron Compounds. *Phosphorus* is available in the elemental state, as organic phosphates, or as inorganic acid phosphates. All forms are used as flame retardants in different polymer systems, e.g., elemental red phosphorus in polyamides, organophosphates in polyphenylene oxides or polyurethanes, and inorganic acid phosphates in cellulosics. In the presence of heat and oxygen, phosphorus compounds decompose to form water vapor and phosphorus oxides. The phosphorus oxides subsequently react with the polymer matrix and dehydrate it, reforming phosphoric acids. These acids again decompose to reform water vapor and phosphorus oxides.

Ultimately as the water available from normal combustion of hydrocarbons diminishes, the phosphorus oxides react with hydrocarbon fragments to produce a very high melting point char at the interface between the polymer and the heat source. The chars, which contain phosphorus, rapidly dissipate heat energy and lose their "glow". This antiglow property of phosphorus contributes to its effectiveness as a flame retardant.

Boron compounds can function in a manner similar to phosphorus compounds. However, elemental boron is not used commercially as a flame retardant. Organoboron compounds are less stable and typically much more expensive than organophosphorus compounds. Inorganic boron compounds are used as extenders for antimony oxide or in low-cost treatments for cellulosics.

Typically, 1 – 10 parts of contained phosphorus or boron is used per 100 parts of polymer. Care should be taken, however, in developing formulations that use both gas-phase and solid-phase flame retardant mechanisms because combinations of halogen, antimony oxide, and phosphorus can be synergistic or antagonistic.

Sulfur Compounds. Some inorganic sulfur compounds, such as ammonium sulfate and ammonium sulfamate, form anhydrous sulfur oxides on decomposition. Sulfur compounds are used almost exclusively as low-cost flame retardants for cellulosics. Sulfur compounds are not used commercially as flame retardants in thermoplastics or other polymer systems, although research is being conducted in this

area. On the basis of improved flame retardancy of poly(phenylene sulfide) nonmigrvs. poly(phenylene ether) as a neat polymer, an improvement in flame-retardant properties from those of sulfur-containing materials vs. oxygenated materials could be predicted.

Silicon Compounds [4], [5]. Organosilicon compounds can decompose to form incombustible silicon oxide structures. For example, organosilicon-containing polymers can be formulated to produce low-density silicone foams with excellent flame-retardant characteristics. Proprietary metallic catalysts, such as platinum, are quite efficient in these systems.

Halogenated phenol organosilicon compounds have been developed and are more efficient than analogous compounds without silicon [4], [5]. This efficiency is probably a result of formation of a char containing silicon oxide, and of the vapor-phase activity of the halogen. Care must be exercised in the choice and use of silicon-containing materials. Finely divided calcium silicates used as thickening agents in polymer systems can adversely affect flame retardation.

Polynuclear Aromatics. Some materials, which form highly condensed aromatic structures when heated, ultimately burn because they are hydrocarbons, but do so with difficulty. Untreated *phenolic polymers* have good flame-retardant properties. However, they can glow and radiate heat for prolonged periods of time after the original heat source is removed and, therefore, can ignite combustible matter in contact with them.

Complex aromatic polyesters resulting from the alkaline hydrolysis of poly(ethylene terephthalate) residues are effective in polyurethane, polyisocyanurate, and hybrid foam systems as char formers. *Isocyanurate foams* show better flame retardation than conventional urethanes because of the more condensed polynuclear aromatic structure. *Polyamides* based on aliphatic diamines and aliphatic diacids have a limited degree of inherent flame-retardant properties. However, polyamides that have aromatic rather than aliphatic reactant groups have been made into fibers with excellent flame retardation. In fact, Nomex fibers can be made into firefighters' uniforms. *Aromatic polyimides* are also inherently flame retardant (→ High-Performance Fibers).

The concept of polynuclear aromatic effectiveness is also used in *additive bromine compounds,* such as decabromodiphenyl oxide [*1163-19-5*] (Saytex 102 flame retardant) and ethylene bis(tetrabromophthalimide) [*32588-76-4*] (Saytex BT-93 flame retardant). In many systems BT-93 is more effective than 102 even though BT-93 has a lower bromine content. Thermal gravimetric analysis shows significant char formation on decomposition for BT-93 and almost none for decabromodiphenyl oxide.

Intumescence [6]. Systems containing a polyhydric alcohol (e.g., pentaerythritol), a nitrogen source (e.g., melamine), and a phosphorus donor (e.g., ammonium polyphosphate) can form thermally stable foams when heated. The major historical use of this intumescent chemistry has been in water-based paints and coatings. Untreated polypropylene has also been flame retarded effectively with intumescent systems, but at high loadings of 30 – 50 parts per 100 parts of polymer. These polymer formulations generate little smoke when burned.

Even under polypropylene processing conditions, care is required to avoid premature foaming of the ingredients. More thermally stable systems have been proposed for styrenic polymers [6]. These systems are reported to produce little smoke and good resistance to ultraviolet light.

3. Test Methods

Test methods have been developed that vary in complexity from simple (e.g., ASTM D 2863 and UL 94, which require specimens that are 10 cm long) to very complex (e.g., ASTM E 84, which require specimens 750 cm long) [7].

Test methods may evolve on the basis of particular requirements of a country or industrial group. In the United States, materials must meet Underwriters Laboratory standards of performance: polymer compositions used in general electrical components must satisfy the UL 94 test; wire and cable compositions, UL 44 or 62; television components, UL 1410. Products going into coal mines in the People's Republic of China must meet standards based on ASTM D 2863. Insulating foams for sale in the

Federal Republic of Germany must be rated by a DIN test.

These tests are conducted on small specimens instead of finished articles, even though configuration does affect flammability results. Many industrial and regulatory authorities have realized the shortcoming of such simplistic test procedures and have developed larger-scale tests on finished articles. *Full-scale burns* of finished electrical wires and cables, foam-upholstered chairs, and total roofing assemblies are now more common. Because of cost, only the largest companies have facilities to conduct these tests. Specialized consulting testing laboratories have emerged to do this work for smaller companies and to provide unbiased data for product acceptance or regulatory purposes for companies of all sizes.

Figure 1. Oxygen index tester, ASTM D 2863 [7, p. 183] a) Pilot flame; b) Burning specimen

ASTM D 2873-77. The oxygen index or limit oxygen index test determines the oxygen concentration at which sustained combustion occurs using a vertically mounted specimen ignited at the upper end (Fig. 1). The test is performed at room temperature, but equipment is available to test for oxygen index at elevated temperature. Results are expressed as $[V_{O_2}/(V_{O_2} + V_{N_2})] \cdot 100\,\%$. Typical oxygen index values (in vol %) for polymers are as follows:

Polyolefins	17.4
Flame-retarded polyolefins	24 – 28
Polystyrene	18.1
Flame-retarded polystyrene	27 – 30
Epoxy resin	24.0
Polyurethane foam	18.0
Rigid poly(vinyl chloride)	40.0
Polytetrafluoroethylene	95.0

The oxygen index test is simple and reproducible and is used to guide development work. Conclusions about fire performance in an actual fire should not be made based on results from the oxygen index test or any other test.

UL 94 of Underwriters Laboratory. The UL 94 test rates materials on the basis of their ability to resist combustion on repeated application of a flame. The test also rates materials for their resistance to dripping with subsequent ignition of a combustible substance (cotton) from the resulting drips.

Test specimens (12.7 × 1.27 cm × various thicknesses) are mounted vertically in a chamber (Fig. 2). Ignition takes place at the lower end of the test specimen. After a 10-s ignition, the flame is removed. If the specimen extinguishes, the afterflame time is recorded and the specimen is reignited for 10 s.

Materials are classified on the basis of afterflame time and ignition of the cotton caused by flaming drips. The most widely accepted classes are 94 V-0, 94 V-1, and 94 V-2. Class 94 V-1 allows a longer afterflame time than 94 V-0, whereas class 94 V-2 has the same afterflame time as 94 V-1 but allows for cotton ignition. Variations of the test utilize different shape specimens and orientations, e.g., horizontal.

Many applications require UL 94 V-0 ratings at very thin sections. Historically, a V-0 rating at 0.32 cm was acceptable; however, more recent products are formulated to achieve a V-0 classification at 0.08 cm. Achieving the V-0 classification at thinner sections is difficult because of the tendency of thermoplastics to melt and drip. Although polymers that drip are permitted by UL 94 V-0, a delicate formulating balance is required to ensure consistent passage of the test.

Because of the worldwide importance of the United States market, companies that export electronic assemblies to the United States manufacture products to the UL 94 standard. This

standard often becomes the accepted norm for products for the individual domestic marketplace as well. Multinational corporations seeking uniformity in many countries also utilize the UL 94 standard to simplify testing.

Figure 2. Underwriters Laboratory, UL 94 ∗ [7, p. 350]
a) Specimen; b) Burner; c) Surgical cotton (ca. 50×50 ×6.5 mm)
∗ Dimensions are in mm.

A) Longitudinal view: a) Test chamber (7.62 m); b) Fire end; c) Vent end; e) Viewing windows
B) Cross-sectional view of section x – y: d) Removable cover plate; e) Viewing windows; f) Gas burner; g) Specimen

ASTM E 84. The ASTM E 84, or Steiner tunnel test (Fig. 3), is used to rate building and construction materials in the United States for their flame spread, fuel contribution, and smoke evolution.

Test specimens (51.43 ± 1.9 cm wide by 629.9 ± 1.27 cm long) are placed in a tunnel and ignited at one end. Ratings are based on the performance of a standard redwood board (flame spread 100) and asbestos board (flame spread 0).

Typically only the flame spread and smoke values are used to rank materials. Local United States building codes often include E-84 values in their material acceptance criteria. Code values for flame spread are 25 for class I and 75 for class II; smoke density values are 450 for both classes, relative to cement – asbestos (0) and red oak (100).

DIN 4102 Part 1. The Federal Republic of Germany rates building and construction materials by this test as noncombustible (A) or combustible with low (B-1), moderate (B-2), or high (B-3) flammability characteristics.

Four specimens (19×100 cm) are mounted around a chimney and ignited from the bottom for 10 min. At the end of the test, specimens are measured and other observations made. To be rated B-1, the mean length of the specimens must still be 15 cm.

In some variations of the DIN test, surface charring is an important test criteria. Thus, the total specimen could still be B-1 by DIN 4102, but surface charring would render it a B-2 or B-3 classification. Some aliphatic bromine compounds are more effective in reducing this surface flash charring than others.

4. System Development

Flaming can be retarded by incorporation of the flame-retardant molecule into the polymer itself or by admixture of the flame retardant with the polymer. The former is the *reactive approach*, and the latter is the *additive approach*.

The major advantage of the reactive approach is the non-migratory nature of the flame retardant. This eliminates mold plate-out or blooming, which often occurs with flame retardants in plastics systems. A secondary advantage is the ability to produce optimum polymer properties by using the proper balance of reactive material and other monomers. Additive-type flame retar-

dants generally reduce some property, such as impact resistance or heat resistance.

Costs associated with reactive systems are usually higher than with additive systems because of the required development of new polymerization technology. Reactive systems may not be as effective as additive systems because of the more controlled availability of the flame retardant. The ability of flame retardants to melt and migrate to the flame front in the heat of a fire is often desirable; such movement is restricted if the flame retardant is part of the polymer backbone.

Typical examples of systems in which reactive flame retardants can be used are polyurethanes, unsaturated polyesters, epoxy resins, and polycarbonates. However, some additive systems exist for each of these polymer classes, and the choice between additive, reactive, or hybrid systems is based on other formulation parameters, such as properties and costs. For example, glass fiber reinforced bathroom showers and tubs are typically produced with high loadings of aluminum oxide trihydrate as an additive flame retardant. Alternatively, a brominated or chlorinated acid or alcohol can be used in forming the polyester resin itself.

4.1. Selection Criteria of Flame Retardants [8]

Identification of the *flammability test requirements* is the initial criterion for selection of the appropriate flame retardant. In some cases, changing part design or construction material obviates the need for flame retardants.

Establishing the desired *cost–performance parameters* is the second key criterion. For example, a UL 94 V-0 polypropylene may be produced with 10 – 100 parts of various flame retardants per 100 parts of polypropylene. The properties and costs of systems containing high loadings of flame retardant are vastly different from those at low loadings.

Environmental exposure requirements of the finished article is a third criterion. For example, unsaturated polyesters based on dibromoneopentyl glycol [*3296-90-0*] have superior resistance to discoloration by UV light compared to products based on tetrabromophthalic anhydride [*632-79-1*]. Ethylene bis(tetrabromophthalimide) has superior resistance to UV light in styrenic polymers compared with halogenated diphenyl oxides. However, television cabinets and computer components are often painted to mask color changes resulting from fluorescent or UV light exposure in preference to using flame retardants with good light resistance. Other special environmental exposure criteria are optical clarity and corrosion resistance.

Aromatic bromine-based flame retardants have resulted in the development of new products that overcame previous performance deficiencies [8]; these compounds are listed in Table 1.

Compounding (or reacting) of the flame retardant must take into account the stability of the flame retardant, the matrix in which it is suspended, and the effect of the flame retardant or its degradation products on processing or compounding equipment. Typically, thermal gravimetric analysis is used to evaluate the decomposition or volatilization of flame retardants and to aid in selection of the most cost-effective material.

4.2. Formulation with Reactive Flame Retardants [9], [10]

Reactive flame retardants must be combined with the polymer during manufacture or be capable of being grafted during subsequent processing. Each flame retardant has a unique technology that provides the desired level of flame retardation and polymer properties.

Polyurethane Foams. Flame-retardant rigid foams can be produced from polyhydroxy-terminated chlorine- and bromine-containing compounds with a nonreactive organophosphate as diluent to reduce viscosity (Solvay IXOL B-251), or from ester ethers of tetrabromophthalic anhydride (Ethyl Saytex RB-79 flame retardant) [*75790-69-1*]. Derivatives of dibromoneopentyl glycol or organophosphates that have a hydroxyl functionality, such as diethyl-*N,N*-bis(2-hydroxyethyl)aminomethyl phosphonate (Stauffer's Fyrol 6) [*2781-11-5*], can also be used. A formulation for a rigid urethane foam that meets ASTM E 84 Class I is as follows:

Table 1. Aromatic bromine-based flame retardants

Bromine compound	CAS registry no.	Bromine, %	*mp*, °C	10 wt %, loss by TgA, ∗ °C
Pentabromotoluene	[*87-83-2*]	82	280	220
Pentabromophenylallyl ether	[*3555-11-1*]	76	163	190
Pentabromoethylbenzene	[*85-22-3*]	80	136	231
Decabromodiphenyl	[*13654-09-6*]	84	375	330
Pentabromodiphenyl oxide	[*32534-81-9*]	71		260
Octabromodiphenyl oxide	[*32536-52-0*]	79	70 – 150	322
Decabromodiphenyl oxide	[*1163-19-5*]	83	300 – 310	365
Ethylene bis(tetrabromophthalimide)	[*32588-76-4*]	67	445	450
Tetradecabromodiphenoxybenzene	[*58965-66-5*]	82	370	420

∗ TgA = thermogravimetric analysis.

Mobay Multranol 4034	18.6 wt %	
Saytex RB-79 flame retardant	28.0 wt %	
Dow Corning 193 surfactant	0.7 wt %	
Abbott Labs Polycat 8	0.7 wt %	
DuPont Freon 11	13.0 wt %	
Upjohn PAPI 135	39.0 wt %	
Isocyanate index	110.0	
Bromine	14.0 wt %	
ASTM E 84 test		
Thickness	5.1 cm	10.2 cm
Flame spread index	25.0	25.0
Smoke density	135.0	65.0

Manufacturers of foam may make their own formulation or may purchase preformulated packaged systems, which come in two or three parts. One part is usually polymeric isocyanate. A second part contains polyol or a polyol mixture, water, flame retardant, silicone surfactant, catalyst, and a blowing agent. Special catalysts may be supplied as a third part.

High-speed, high-intensity mixers are used to ensure adequate mixing. Reaction takes place between hydroxyl groups and isocyanate groups:

As the complex structure begins to form, heat is generated, the fluorocarbon blowing agent volatilizes, and the foam rises. Cross-linking occurs between the active hydrogens of the carbamate groups with additional isocyanate.

Polycarbonates are produced in complex systems containing both aqueous and organic phases. The reaction between bisphenol A [*80-05-7*] and phosgene [*75-44-5*] is as follows:

A reactive flame-retarded polycarbonate is produced by substituting tetrabromobisphenol A [*79-94-7*] or another halogenated biphenol for some of the bisphenol A.

Unsaturated Polyesters [11]. Polyesters are produced by reacting glycols with organic acids. Typical ingredients are ethylene and propylene glycols and phthalic or maleic anhydride. Acid anhydrides are preferred because they generate only half as much water of reaction as the corresponding diacid. Esterification catalysts, such as *p*-toluenesulfonic acid or titanium complexes, are often used.

Unsaturated polyesters contain maleic anhydride or tetrahydrophthalic anhydride, which results in aliphatic unsaturation of the backbone. These polyesters are capable of further cross-linking with styrene, divinylbenzene, or another vinyl monomer to produce highly rigid, complex networks. The styrene – unsaturated polyester systems are usually further reinforced with fiberglass to produce a wide range of products from bathtubs to boats.

When flame retardation is required, halogens, most often chlorine or bromine, are selected. The halogen is introduced in several ways:

Table 2. Formulation of two typical flame-retardant unsaturated polyesters containing tetrabromophthalic anhydride

Component	mol	mol
Tetrabromophthalic anhydride	0.40	0.73
Phthalic anhydride	0.60	0.27
Maleic anhydride	1.00	1.00
Ethylene glycol	2.06	
Propylene glycol		2.06
% Bromine	18.0	25.0
Oxygen index	34.3	34.0

Table 3. Formulation of a flame-retardant unsaturated polyester containing dibromoneopentyl glycol

Component	mol
Part A ∗	
Maleic anhydride	1.9
Phthalic anhydride	1.9
Dibromoneopentyl glycol	4.0
Part B ∗	
Maleic anhydride	4.5
Phthalic anhydride	4.5
Propylene glycol	10.0

∗ Part A contains 30 wt % bromine and part B contains no bromine; the two parts are mixed to achieve 21 wt % bromine.

1) Direct bromination of the unsaturated aliphatic polyesters (Koppers Dion resins)
2) Dibromoneopentyl glycol [*3296-90-0*] as a replacement for ethylene or propylene glycols (Dow Chemical FR-1138 or Dead Sea Bromine FR-522)
3) Hydroxyethylated tetrabromobisphenol A [*4162-45-2*] as a replacement for a portion of the glycols
4) Tetrabromophthalic anhydride as a replacement for a portion of the phthalic anhydride (Ethyl Saytex RB-49 flame retardant or Great Lakes Chemical PHT-4)
5) Chlorendic anhydride [*115-27-5*] (Velsicol Chemical Co.) as a replacement for a portion of the phthalic anhydride
6) Tetrachlorophthalic anhydride [*117-08-8*] (Monsanto Tetraphthal) as a replacement for a portion of the phthalic anhydride
7) Diallyl tetrabromophthalate [*49693-09-6*] to replace some or all of the cross-linking styrene
8) Halogenated styrene of divinylbenzene to replace some or all of the cross-linking styrene

Cost and product performance are the controlling variables in selecting the flame retardant. Typical formulations containing tetrabromophthalic anhydride or dibromoneopentyl glycol [11] are shown in Tables 2 and 3.

Epoxy Resins. Epoxy resins are produced from the reaction of bisphenol A and epichlorohydrin (→ Epoxy Resins). Reaction conditions are chosen carefully to ensure consistency of epoxide concentration in the resin. Of particular concern are trace impurities, such as inorganic halides, that remain in the finished product. Inorganic halides can adversely affect electrical properties in finished epoxy resin–glass fiber printed circuit boards. Organic halides that are readily hydrolyzed by mild alkali can interfere with the rate and extent of cure. Most epoxy resin manufacturers stress consistency of both hydrolyzable and ionic halides so that users need not make changes in their formulation or operation.

Table 4. Formulation of a low-bromine flame-retardant epoxy resin

Component	parts by wt
Solution A	
Shell Epon 828 resin	64.57
Saytex RB-100	35.43
Triphenyl phosphine	0.20
Acetone	25.00
Solution B ∗	
Resin solution A	125.20
Dicyandiamide	2.90
Benzyldimethylamine	0.20
Acetone or methyl cellosolve	75.00

∗ Solution B is used to make the glass laminates.

Flame-retarded epoxy resins are made by using tetrabromobisphenol A to partially or almost totally replace the bisphenol A. These resins contain either 20 or 40 wt % bromine and are referred to as low bromine and high bromine, respectively. The choice of which resin to use is based on the flame-retardant requirements of the printed circuit board or other application.

Typical FR-4 board manufacture. Printed circuit board stock is manufactured from catalyzed epoxy resins and glass cloth. The resin is applied in an impregnating bath. Partial curing or B staging occurs so that the glass cloth can be handled but is not too tacky or sticky. Multilayers of the B-staged cloth and copper foil are placed in a

curing press, and the lamination is then formed and cured (→ Epoxy Resins, Chap. 4.2.1.).

A typical low-bromine epoxy resin formulation is given in Table 4.

Printed circuit boards are also made with polyester or phenolic resins. The polyester boards are based on brominated resins with antimony oxide synergist. Phenolic boards often contain brominated diphenyl oxides and occasionally a phosphate plasticizer or diaminodiphenylsulfone.

Halogenated monomers , if available, can be used to make inherently flame-retarded polymers, such as vinyl chloride [*75-01-4*] in poly(vinyl chloride) or ethylene – vinyl chloride copolymers. Vinylidene chloride [*75-35-4*] resins are also inherently flame-retardant. Vinyl bromide [*593-60-2*] is copolymerized with acrylic monomers in flame-retardant carpet fiber applications.

Halogenated styrene monomers have been investigated to find compounds having high halogen content, adequate storage stability, and a satisfactory reaction rate. Although development quantities of both chloro- and bromostyrenes are available, none have achieved commercial success.

Acrylic or allylic monomers with pendant tribromophenol [*118-79-6*] or pentabromophenol [*608-71-9*] groups are also available. These can be either co- or homopolymerized. The homopolymer itself can be used as a flame retardant. Two examples of polymeric or oligomeric flame retardants from halogenated monomers are poly(dibromophenylene oxide) [*26023-27-8*] (Great Lakes PO-64P), made from 2,4,6-tribromophenol [*118-79-6*]; and poly(pentabromobenzyl)acrylate [*59447-57-3*] (Dead Sea FR-1025), made from pentabromobenzyl bromide [*38521-51-6*].

Glycidyl derivatives of brominated phenols have also been manufactured and have many uses.

4.3. Formulation with Additive Flame Retardants

Compounds and formulations with additive flame retardants depend on the polymer matrix and the end-use requirements [12–17]. Combinations of chain-stiffening and plasticizing flame retardants to achieve an optimum balance of properties in thermoplastics have been described [16], [17].

The major emphasis in this section is on additives used in conjunction with thermoplastics. Instead of the reactive flame retardants discussed in Section 4.2, additives may be used in the same polymer systems as follows:

1) polyurethane foams – organophosphates, brominated organics, alumina trihydrate
2) polycarbonates – brominated organic oligomers, sulfonate salts
3) unsaturated polyesters – brominated organics, alumina trihydrate
4) epoxy resins – brominated organics

Laboratory Compounding [1], [18], [19]. The equipment used for laboratory compounding of thermoplastics, such as polyolefins, styrenics, and polyesters, depends on the characteristics of the polymer, flame retardant, and other additives.

Typically the polymer is fluxed, masticated, or otherwise prepared for acceptance of the flame retardant mixture. When both halogenated flame retardant and antimony oxide are used, they are preblended and added to the fluxed polymer. In general, the procedures and equipment for thermoplastics are also used for thermoplastic or thermosetting elastomeric polymers.

Three types of laboratory equipment are employed:

The laboratory *Brabender Plasticorder* has two counter-rotating, intermeshing, shear kneading rollers that masticate the polymer. Heat is provided electrically.

A typical compounding *mill* has two counter-rotating chrome-plated steel rolls, which run at different speeds to increase shearing and mixing, and can be individually heated or cooled.

The Haake compounding twin-screw *extruder* has two intermeshing screws and a single drive. More complex equipment has independent drives with either concurrent or countercurrent rotation. Heat is varied along the barrel to increase or reduce melt viscosity and shear. Some equipment has an individual port along the barrel for addition of various ingredients or for venting off-gas.

Table 5. Thermoplastics processing temperatures

Polymer	Operating temperature, °C		
	Brabender	Mill	Extruder
Acrylonitrile – butadiene – styrene	175	170	170
Polystyrene (high-impact)	190	175	175 – 200
Polypropylene	175	210	175 – 200
Polyethylene (low-density)	120	140	
Polyethylene (high-density)	175	165	175 – 200
Polyamide	260		260 – 270
Poly(butylene terephthalate)	270		240 – 260
Poly(ethylene terephthalate)	270		240 – 260

Operating temperatures for the three types of plastics compounding equipment are shown for a variety of polymers in Table 5.

Once the plastic mass has been well compounded, finished plaques for further testing are formed by compression molding in standard heated presses or by injection molding. Molding conditions for some thermoplastics are shown in Table 6.

Table 6. Thermoplastics injection molding

	Temperature, °C	Pressure, MPa
Polyethylene	190 – 260	3.6 – 3.8
Polypropylene	230 – 275	3.6 – 3.8
Poly(vinyl chloride)	175 – 200	3.4 – 3.8
Polystyrene (crystalline)	220 – 260	4.0 – 4.1
Polystyrene (high-impact)	205 – 230	4.0 – 4.1
Acrylonitrile – butadiene – styrene	220 – 260	3.6 – 4.1
Poly(ethylene terephthalate) (glass filled)	235 – 275	3.6 – 4.1
Poly(butylene terephthalate) (glass filled)	230 – 275	3.8 – 4.1
Polyamide 6 and Polyamide 66 (natural resin only)	275 – 295	3.4 – 3.6
Polycarbonate (natural resin only)	260 – 295	3.4 – 3.6

Test specimens are evaluated for flame retardation and for other physical properties. These tests are also used in thermoplastic or thermosetting systems based on reactive flame retardants. Typical property tests are

Heat distortion temperature	ASTM D 648
Vicat softening point	ASTM D 1525
Izod impact strength	ASTM D 256
Dart drop resistance	ASTM D 1709
Tensile – elongation	ASTM D 638
Flexural strength	ASTM D 790

In almost all cases, flame-retardant additives reduce the impact strength of virgin polymers. Very high-melting or reinforcing flame retardants increase thermal deformation resistance, whereas low-melting flame retardants reduce thermal deformation resistance. Flexural strength and tensile strength are increased with high-melting flame retardants, but percent elongation is reduced. Table 7 shows the wide divergence in some physical properties attainable in an acrylonitrile – butadiene – styrene polymer with five flame retardants [8].

Chlorine and bromine flame-retardant compounds have been compared in wire and cable compositions [18]; retardants for thermoplastic polyurethanes have been described [19]. Differences in flame retardation were observed between ester and ether polyurethanes.

Commercial Compounding. Commercial equipment varies only slightly from the laboratory counterparts. Mills are larger or contain three rolls rather than two. Extruders are also larger.

In place of the Brabender, commercial facilities use Banburys with various designs of kneading devices. The Farrel continuous mixer (FCM, Farrel Manufacturing Co.) combines some of the features of both a Banbury and an extruder. The FCM has two counter-rotating mixing motors similar to a Banbury. The ends of the rotors are extended with screw flights evolving into a metering twin-screw extruder. The plastic is continuously extruded through a pelletizer die.

The producer of a television set, for example, purchases a molded cabinet from a custom molder. The molder purchases plastic pellets from a manufacturer who warrants that the plastic meets a UL 94 V-0 rating. The pellet manufacturer has the following two options:

1) Mix base resin with flame retardant and antimony oxide and make a finished compound in pellet form.

Table 7. Properties of flame-retardant acrylonitrile – butadiene – styrene polymers

	Neat resin	DBDPO[a]	OBDPO[b]	TDBDPB[c]	TBBPA[d]	HBDPE[e]
Oxygen index	18.4	27.1	28.3	31.2	33.7	25.8
UL 94 (0.32 cm[f])	burn	V-0	V-0	V-0	V-0	V-0
(0.16 cm[f])	burn	V-0	burn	V-0	V-0	burn
Tensile strength, MPa	36	40	44	39	33	40
Flexural modulus, GPa	2.2	1.7	2.0	2.3	2.7	2.0
Vicat softening point (0.32 cm[f]), °C	100	102	97	102	85	96
Izod impact strength (0.32 cm[f]), J/m	34.3	6.9	13.7	5.9	4.9	12.8

[a] Decabromodiphenyl oxide.
[b] Octabromodiphenyl oxide.
[c] Tetradecabromodiphenoxybenzene.
[d] Tetrabromobisphenol A.
[e] Bis(tribromophenoxy)ethane.
[f] Sample thickness.

2) Mix base resin with a premixed concentrate of flame retardant and antimony oxide purchased from a concentrate manufacturer. These concentrates, which can contain up to 90 wt % of active material with 10 wt % binder, are "let down" with base resin to the desired level of active ingredient in the finished compound.

Although individual manufacturers are the best source of specific formulation information, following are some typical flame-retardant systems for various thermoplastics. All are based on 100 parts of original base polymer. Unless otherwise indicated, the formulations give UL 94 V-0 compositions of 0.32 cm thickness.

High-impact polystyrene: 14 parts decabromodiphenyl oxide with 4.75 parts of antimony oxide.

Acrylonitrile – butadiene – styrene (ABS):

A total of 23 parts of octabromodiphenyl oxide [*32536-52-0*] with 5 parts of antimony oxide, or 34 parts of tetrabromobisphenol A and 8.6 parts of antimony oxide.

Polypropylene:

A total of 4 parts of ethylene bis(5,6-dibromonorbornane-2,3-dicarboximide) (Ethyl Saytex BN-451 flame retardant) [*41291-34-3*], or bis(2,3-dibromopropyl ether)tetrabromobisphenol S (Great Lakes Chemical PE68) [*21850-44-2*], or bis(2,3-dibromopropyl ether) tetrabromobisphenol S (Marubishi Non-Nen 52) [*42756-55-1*] with 2 parts of antimony oxide produces UL 94 V-2 formulations. Ten parts of Non-Nen 52 with four parts of antimony oxide produces a V-0. Intumescent formulations based on pentaerythritol, phosphorus donor, and melamines produce a V-0 rating at 24 – 40 parts per 100 of polymer; V-0 is also achievable with 40 – 80 parts of aluminum oxide trihydrate or magnesium hydroxide (hydrated magnesia).

Glass-reinforced (30 wt %) poly(buylene terephthalate) (PBT) or poly(ethylene terephthalate) (PET):

several products are used commercially such as tribrominated polystyrene (Ferro Pyrochek 68PB) [*57137-10-7*], polycarbonate oligomers of tetrabromobisphenol A (Great Lakes Chemical BC-52 [*28906-13-0*] or BC-58 [*71342-77-3*]), poly(dibromophenylene oxide) (Great Lakes Chemical PO64P), decabromodiphenyl oxide or ethylene bis(tetrabromophthalimide) (EthylSaytex BT-93 flame retardant). From 6 to 8 wt % aromatic bromine with 3 – 5 parts of antimony oxide are used. Actual levels of the flame-retardant compound itself are adjusted on the basis of its individual bromine content. The ratio of brominated compound to antimony oxide is generally 2 – 3 : 1. However, in countries such as the People's Republic of China, where antimony oxide is plentiful, economics often dictate the ratio of materials, with the result that more antimony oxide is used.

Systems not containing glassrequire a higher amount of flame retardant. Levels are increased to 10 – 14 % of contained bromine and 4 – 8 parts of antimony oxide.

Low-density polystyrene foam:

A total of 1 – 2 parts of hexabromocyclododecane [*3194-55-6*], pentabromomonochlorocyclohexane (Dow Chemical 651P) [*87-84-3*], and dibromoethyldibromocyclo-

hexane (Ethyl Saytex BCL-462 flame retardant) [*3322-93-8*] are adequate to produce foam that meets building code requirements in the United States; UL 94 values on these foams are not significant.

Poly(phenylene oxide) high-impact polystyrene blends:

A total of 15 – 20 parts of an aromatic phosphate, such as triphenylphosphate [*115-86-6*], in nominal 50 : 50 blends of the two polymers.

In addition to their use in plastics, flame retardants are also necessary in other polymer systems, such as elastomers, textiles, paints, paper, and coatings. Where processing temperatures or environmental exposure requirements are not severe, chlorinated alkanes can economically replace brominated organics. Where mass per unit volume or physical properties are not critical, aluminum oxide trihydrate or other fillers can replace more expensive flame retardants.

Commercial applications of the flame retardant are a function of end-use requirements. For example, flame retardants can be made an integral part of a polypropylene upholstery or carpet fiber through melt processing or can be applied to the finished fabric as a back coating. In the former case, the retardant must be fluid at the spinning temperature or be a fine, uniform particle size powder. Either a liquid or solid flame retardant can be used for back coating; decabromodiphenyl oxide dispersed in a latex binder system is used widely for polypropylene drapery or upholstery fabric.

Clothing has also been treated for flame retardation with a variety of halogen- and phosphorus-containing materials. Of particular concern are the effects of the chemicals on direct skin contact. Durability to washing and dry cleaning are also critical factors. Finally, the flame retardant must not affect the fabric color or feel. In most cases, proprietary formulations, which are specific for fiber content, have been developed. Testing of flame-retarded fabrics is by both horizontal and vertical procedures.

Paper is also flame-retarded. Typical nondurable systems are based on inorganic salts, such as ammonium phosphates and sodium borates. More durable flame retardants are based on chlorine-containing emulsion polymers synergized with antimony oxide. The flame retardants are most often applied to the paper in a saturation or coating operation.

4.4. Interactions between Flame Retardants and Other Formulation Ingredients

Fillers. Calcium carbonate can interfere with the flame-retardant action of halogenated flame retardants because it absorbs and neutralizes HCl or HBr. Carbon blacks, with high levels of residual oils on their surface, make flame retarding difficult in any system. Fine-particle colloidal silica used to minimize dripping in flame-retarded thermoplastics also contributes to increased flammability because of its high surface area.

When high loadings or fillers are used, dispersion is difficult and the effect on polymer physical properties is significant. Fillers with surface treatments of organotitanate or organosilicon coupling agents are useful to overcome the dispersion and physical property loss problems. In some instances flame retardance has been improved because of the addition of a coupling agent.

Some evidence even suggests that aluminum oxide trihydrate or magnesium hydroxide at low loadings can act synergistically with halogen antimony oxide systems.

Colorants. Some inorganic cadmium and zinc pigments are deleterious to flame retardation. The mechanism for this phenomenon is unknown.

Thermal Stabilizers and Processing Aids. Zinc-based processing aids can cause discoloration of a polymer matrix when used in combination with halogenated materials. Calcium stearates are generally used when this problem occurs. Depolymerization of styrenic polymers caused by some halogenated flame retardants during polymer processing can be minimized by organotin systems. These systems also usually contain complex phenolic antioxidants, such as Irganox 1010 (Ciba-Geigy) [*6683-19-8*], Ethanox 330 (Ethyl) [*1709-70-2*], and occasionally thiols.

Synergists [20]. Tin compounds are effective synergistic agents as partial or total replacements for antimony oxide [21]. A total flame retardant for polypropylene is reported to contain 32 % bromine, 1 % phosphorus, and 1.5 % tin.

Phosphites can act synergistically with certain brominated flame retardants in the absence of antimony oxide. In other systems containing antimony oxide, loss of flame retardation has been observed with phosphites.

Peroxide-producing chemicals, such as 2,3-dimethyl-2,3-diphenylbutane [*1889-67-4*], can be used in combination with aliphatic or cycloaliphatic bromine compounds in styrenic polymers. Additive levels of the bromine can sometimes be significantly reduced by as much as 50 % in polystyrene foam manufacture.

Combinations of zinc borate [*12536-65-1*] and antimony oxide mixed with decabromodiphenyl oxide or ethylene bis(tetrabromophthalimide) are used in wire and cable formulations based on thermoplastic styrene – butadiene copolymers. Higher oxygen indices are obtained with these mixtures than with antimony oxide alone.

Ultraviolet Light Stabilizers and Antioxidants (→ Antioxidants, Chap. 5.4.), [22–24]. Each polymer system with its flame retardant is unique and requires a specific stabilization package. What is acceptable in high impact polystyrene or ABS may be totally ineffective in alloys or blends of these substances with other polymers.

Consistency of color under exposure to ultraviolet or fluorescent light has become a critical issue in business machines and other plastic cabinetry. It is equally important in fabrics, paints, and coatings.

Impact polystyrene containing an aromatic bromine or an aliphatic bromine – chlorine compound has been studied with a wide range of light stabilizers in combination with antioxidants [22], [23]. In all cases, the flame-retarded impact polystyrene had poorer light stability than the polymer alone.

Benzotriazoles combined with hindered phenolic antioxidants were most effective with aromatic bromine-based flame retardants. Further color improvement was obtained by adding an epoxy novolac. The system containing an aliphatic halogen compound was improved with benzotriazoles. Hindered amines were effective when combined with benzotriazoles.

Flame retardants that are stable to UV light have been developed. However, the most demanding applications require additional UV stabilizers. The UV stability of brominated flame retardants has been rated as follows [8]:

1) brominated diphenyl oxides: poor
2) bis(tribromophenoxy)ethane (Great Lakes Chemical FF680) [*37853-59-1*]: good
3) ethylene bis(tetrabromophthalimide) (Ethyl Saytex BT-93 flame retardant): excellent

4.5. Formulation to Reduce Smoke

All burning materials generate smoke as a result of incomplete combustion. Styrenic polymers and polyurethanes, for example, produce thick black, carbonaceous, sooty smoke. Flame retardants that interfere with the normal combustion process change the rate of smoke evolution and the amount and composition of the smoke. Less smoke allows individuals more time to safely exit from confined areas.

Much of the development work on smoke suppression has been done with poly(vinyl chloride). Zinc borate reduces smoke and can be used as a partial replacement for antimony oxide in some formulations. Molybdenum compounds are also used in PVC formulations.

Unfortunately, PVC smoke reduction technology has had limited success in other polymers. Molybdenum compounds do function in unsaturated polyesters, however.

Iron compounds, such as ferrocene (Arapahoe DFR-121) [*102-54-5*], have been used in poly(vinyl chloride) and polyurethanes. Iron compounds have also been reported to reduce smoke in polyamide formulations that contain chlorinated organic flame retardants and antimony oxide.

Other metals, such as lead or bismuth, have had limited applications as have quinoline [*91-22-5*] and phthalocyanine complexes. Typically from 0.5 to 6 parts of smoke suppressant per 100 parts of polymer are used.

Smoke from halogen – antimony oxide formulations can be eliminated by using other flame

retardants. Aluminum oxide trihydrate and magnesium hydroxide do not generate smoke. Intumescing systems based on pentaerythritol, a phosphorus donor, and melamine also do not materially contribute to smoke.

Measurement of Smoke Evolution [21], [25], [26]. Smoke is measured peripherally to flammability in some tests, such as ASTM E 84, and independently in others. Smoke measurement testing by small-scale laboratory techniques and full-scale experiments has been reviewed [21].

Little correlation between test methods was observed, as each initiates combustion with different energy input and either a fixed volume or moving air stream. Some protocols include either a radiant energy source or a flaming source as the combustion initiator. Most are based on some form of visual observation; however, the Arapahoe smoke test (ASTM D 4100) rates materials by mass transfer per unit time from the specimen to a collecting filter.

Smoke measuring devices and smoke reduction techniques in olefin polymers have been studied [25].

The most widely used device in the United States is the National Bureau of Standards Chamber (ASTM E 662). The chamber is shown in Figure 4.

The Ohio State University release rate apparatus is gaining acceptance. This device monitors smoke continuously as it exits the apparatus. Since air flow rates can be varied, actual fire situations can be simulated more closely than with the fixed-volume, static ASTM E 662 procedure. Flame retardants that reduced smoke levels significantly have been found using the device [24].

5. Flame Retardant Markets [27–32]

Modern Plastics magazine publishes an annual listing of the major classes of flame retardants in the United States [27]. Included in the article are new products that have appeared in the trade press. Table 8 is the September, 1985 list of major flame-retardant types and their consumption.

Flame retardants in the United States were the subject of studies by SRI International [28]. Updates appear in SRI's tabulations of plastics additives and specialty chemicals. The growth in consumption of flame-retardant chemicals in Western Europe from 1985 to 1992 is shown in Table 9 [32]. The Japanese market for flame retardant chemicals was estimated to be 80×10^3 t in 1984. Japan is the predominant consumer in the Far East, although Taiwan, Korea, and the People's Republic of China are growing users. There are smaller users in South America and South Africa.

Table 8. Consumption of flame retardants by type * [27]

Type of flame retardant	U.S. consumption, 10^3 t	
	1984	1985
Additives		
Aluminum oxide trihydrates	91.8	93.7
Antimony oxides	15.0	15.9
Boron compounds	5.0	5.0
Bromine compounds	15.0	16.9
Chlorinated alkanes and cycloaliphatics	15.0	13.0
Phosphate esters		
Nonhalogenated	16.9	17.0
Halogenated	11.0	11.0
Others **	8.0	8.1
Total	177.7	180.6
Reactives		
Epoxy resin intermediates	11.0	10.0
Polycarbonate intermediates	3.0	3.0
Polyester intermediates	5.0	5.9
Urethane intermediates		
Flexible foam	1.0	1.0
Rigid foam	4.0	4.0
Others	4.0	4.0
Total	28.0	27.9
Grand total	205.7	208.5

* Include secondary plasticizers with flame retardant functionality.
** Include molybdenum, zinc, and metal oxides.

Electronic, electrical [29], and construction [30] applications use the bulk of flame retardants. Wire and cable applications represent a significant specialty subset of electronics and electrical [31].

The Fire Retardant Chemicals Association, with headquarters in Lancaster, Pennsylvania, was formed to allow a common forum for discussion and interchange on matters of concern to manufacturers and users of flame retardants.

Listings of suppliers of flame retardants in the United States are given in the SRI report [28], and lists of suppliers on a worldwide basis including the United States, Europe, and Japan are available [2].

Markets for flame retardants were developed after governmental regulatory action; loss of life

Figure 4. National Bureau of Standards (NBS) smoke chamber, ASTM E 662 [7, pp. 394, 395]
A) View of chamber: a) Door with glass window; b) Blow-out panel; c) Controls and measuring instruments; d) Photometer; e) Window for optical system; f) Test chamber; g) Photodetector housing
B) Operational schematic: a) Light source; b) Light beam; c) Photodetector; d) Photometer; e) Infrared radiator; f) Specimen; g) Trough for specimen melt; h) Six-tube burner

and property because of fire resulted in public pressure to provide "safer materials." Insurance companies also exerted pressure by increasing payment rates in unprotected environments. Pressure still exists for improved products with lower levels of smoke and with reduced toxicity of the combustion products.

Table 9. Estimated West European consumption of flame-retardant chemicals

Product group	Consumption, 10^3 t	
	1985	1992
Polystyrene	4.0 – 4.5	4.5 – 5.0
ABS	1.0 – 1.5	1.2 – 1.8
Polyesters	7.5 – 8.0	8.5 – 9.0
Epoxy resins	3.5 – 4.0	4.0 – 4.5
Polyolefins	10.0 – 12.0	11.0 – 13.0
Poly(vinyl chloride)	25.0 – 27.0	27.0 – 29.0
Polyurethanes	12.0 – 13.5	13.5 – 15.0
Engineering plastics	1.5 – 1.8	1.7 – 2.0
Paper and textiles	9.0 – 10.0	10.0 – 11.0
Rubber and elastomers	5.0 – 6.0	6.0 – 7.0
Other	11.5 – 11.7	12.6 – 12.7
Total	90.0 – 100.0	100.0 – 110.0

Electrical and Electronic Applications. Cabinets and housings for television sets and the polymeric components in the sets (e.g., connectors) must meet flammability standards. Printed circuit boards and internal wires are also processed with flame retardants.

All commercial wires and cables along with connectors, plugs, and spacers are treated with flame retardants.

Construction. Thermal insulating materials are flame retardant. Molded fiberglass units to be used as tubs and shower stalls must meet flammability standards. Institutional mattresses represent a specific use of flame retardants. Furniture cushioning of all types is under active flame retardant development.

Transportation. Polymer components inside mass transit vehicles (airplanes, buses, and subways) must meet flammability standards. Most polymeric materials in private automobiles are flame-retardant, but comply with different flammability standards than mass transit vehicles. Smoke and toxic gas generation from burning vehicle interiors are a significant concern in restricting free exit. Seating material is a major problem because of its total mass in the vehicle and accessibility to accidental or deliberately set fires.

Fabrics and Apparel. Children's sleepwear is subjected to flammability standards, as is workers' clothing in specific industries. Carpets and draperies are treated with flame retardants. Military fabrics, such as tenting, are flame-retardant.

6. Toxicology

Regulatory Influences. The development and introduction of new materials are becoming complex. Information is required by regulatory agencies on the health, safety, and disposal of the product and on its raw materials and byproducts. Often, expensive and lengthy toxicology testing is required prior to commercialization. This testing can include developmental toxicology, as well as teratology.

Workers are becoming more concerned with the long-term safety and health effects of the chemicals they handle and use. Tris(2,3-dibromopropylphosphate) [*126-72-7*] has been banned for use in children's sleepwear, but other uses have not been banned in the United States. The Federal Republic of Germany is evaluating legislation that would restrict the use of chemicals containing or generating chlorinated dibenzoparadioxins. The Japanese Ministries require detailed testing on the effects of chemicals on various fish species.

The regulatory climate and its cost will hinder development of new materials and will emphasize compounding already existing products as much as possible.

Toxic Products of Combustion [32–36]. When materials burn, they liberate both gaseous and solid combustion productions. Inhalation of these decomposition products can cause both short-term and long-term effects. Flame retardants alter the combustion process so that the decomposition products are different from non-flame-retarded materials. The entire process is dynamic, with the composition of liberated gases varying with time.

The evaluation of the toxic effects of combustion products has only recently received significant attention. Toxicity of combustion products is important with materials exposed to fire, but the situation should be viewed together with other aspects of a material's performance, not independently. Resistance to ignition, reduction in the rate or extent of flame spread, and minimization of smoke evolution are all effects produced by flame retardants, which result in the saving of life and property. Combustion toxicity should be included in an overall hazard index with proper emphasis on other protection benefits.

Currently, an accepted standard method for measuring combustion toxicology does not exist. More work is needed in evaluating laboratory tests before material-restricting regulations can be formulated on the basis of the test results [33]. Material design with total fire safety in mind is essential [34].

Time and concentration factors in combustion toxicology have been evaluated [34]. Both are important in determining short- and long-term toxicologic effects. Because fires are dynamic, both time and concentration of various toxicant gases change. Reducing this complex situation to laboratory testing of relatively pure substances is a difficult, if not impossible, task.

Some chair-seat cushioning material produces more toxic gases under smoldering ignition than others [35]. The toxicologic effects of thermoplastics have been compared at normal processing temperatures and above [36]. At some elevated temperatures, Douglas fir had a higher irritation potency than many of the plastics although the effect was more transitory. Large amounts of carbon monoxide were liberated from commercial plastics formulations with and without a flame retardant at temperatures significantly above normal processing temperatures.

Several states in the United States are reviewing toxicity of products of combustion data to determine whether or not regulatory action is required. Political activists in the Federal Republic of Germany are pressing for a ban on certain flame retardants because they produce toxic combustion products.

7. Future Directions in Flame Retardants

New Market Requirements. Flame retardants are used only when this is required by the marketplace. Market changes can increase

or decrease the usage of flame retardants. Although few regulations exist in South America, multinational companies producing subassemblies for the United States, Japanese, or European markets meet the importing country's flame retardant requirements. To ease inventory and production problems, the same companies make flame retardant assemblies for domestic consumption.

Polyurethane and polystyrene foams are efficient thermal insulators per unit thickness, but are more combustible than traditional materials, such as rock wool or fiberglass. Flame retardants are required, therefore, as these materials replace conventional insulation. Other polymer foams (isocyanurate and phenolic) have inherent flame retardance but are deficient in physical properties.

Glass fiber reinforced epoxy printed circuit boards and phenolic paper boards are flame retarded. These low-cost mass-produced articles have been used widely. Developments in flexible circuitry and molded circuits have overcome the rigidity of previous materials. Many high-performance polymers (e.g., polyimides) used in newer circuits are inherently flame retardant.

Specification Changes. Electronic cabinetry is almost exclusively rated UL 94 V-0, with some rated UL 94 V-2. This evolved from electron-tube-powered television sets, where heat evolution from the tubes could result in fire. With the advent of transistorized circuitry with little heat output, no commensurate change was made in the flammability test requirement. An effort is under way to modify the internal configuration of electronic components, shield them, and thus totally eliminate the possibility of their causing plastics ignition. If the rating does change, the need for flame retardants would be reduced or eliminated.

On the other hand, institutional bedding and mass transit vehicles are developing more stringent requirements for flame retardants. The effort to thwart damage results from purposeful and accidental ignition.

1. Introduction

1.1. The Chemical Senses

The sensations "taste" and "odor" are part of our five senses. Whereas seeing, hearing, and feeling react to a physical input (visible light waves, sound waves, and temperature and pressure, respectively) the two so-called chemical senses are stimulated by direct interactions with defined chemicals. The chemical senses are regarded phylogenetically as the oldest senses, i.e., the earliest living species communicated by emitting and receiving chemical signals in their aqueous environment. This communication system was refined when the first species left water to live on land and had to rely on molecules that were transported in the surrounding atmosphere. These molecules had to be volatile and were detected by the odor receptors which consequently developed to a much higher sophistication than the taste receptors. The currently accepted doctrine is that only four basic taste impressions (salty, sweet, sour, and bitter [1]) exist, whereas the types of odor impressions are unlimited. Newer results, however, indicate that the limitation to only four taste impressions is too narrow and that more complex stimulations to the sense of taste do exist [2].

According to E. L. Wick, the term flavor as sensory impression results from the simultaneous stimulation of the two chemical senses, odor and taste [3], so the description of volatile materials will cover both flavor and fragrance materials. As mentioned above, the sense of odor developed to a much higher degree than the sense of taste and in some highly developed mammals (e.g., all canine species) became the most important sense of all. Even in humans, where the sense of sight has become predominant, odor influences considerably the behavior, consciously and subconsciously, it controls for example intake of food and emotions and according to Proust helps in the "search for the past".

1.2. Definition

Flavor and fragrance compounds are molecules that stimulate the human chemical senses. The physiological importance of compounds that elicit a sensory reaction in other living beings apart from humans will not be treated in the context of this paper.

In the following only compounds that stimulate the sense of smell for flavors and fragrances are discussed. These compounds, that are detected in the upper end of the nose have to have a certain volatility to be transported with the aspired air stream to the receptors. It is generally assumed that compounds with a molecular mass > 300 are not volatile enough to fulfill these conditions. Even if many compounds are used both as flavor and fragrance ingredients, some distinctions exist: in general, flavor compounds consist of molecules that occur naturally in edible materials whereas many fragrance compounds are not produced in nature (see Section 1.5).

1.3. History

The history of odor is as old as the history of mankind. Incense was already offered to the God of the Sea in Ninive, in 5000 B.C. The Gilgamesch Epos, which is considered to be the oldest written document about the genesis

of mankind, mentions the use of cedarwood as source of odorants already in 3200 B.C. Sandalwood is described as part of the gifts that the Queen of Sheba gave to Salomon. Greeks and Romans used oil extracts of herbs and flowers as therapeutic agents and for their sensory pleasures. During the middle ages, no real progress in preparing and using odorant materials was reported, apart from the discovery of making concentrated alcohol by the Arabs [4]. Real progress in preparation of odorant compounds and mixtures started nearly simultaneously with the beginning of organic chemistry which is marked by WÖHLER's synthesis of urea [5].

Already in 1830, WÖHLER and LIEBIG synthesized benzaldehyde, which was subsequently identified as the main aroma compound in bitter almonds by ROBIQUET and BOUTRON-CHARLARD in 1932. Worthy of mention is the synthesis of vanillin by REIMER and THIEMANN in 1876, which led to the foundation of the German flavor and fragrance industry.

Analysis of food flavors proved to be cumbersome due to the very low natural abundance of these molecules and the analytical methods available at that time. By 1960, about 450 molecules had been identified to occur in the volatile part of edible materials.

The real breakthrough in knowledge about the chemical nature of odorants started with the invention and application of gas chromatography by JAMES and MARTIN [6]. This analytical and also preparative separation method is the technique of choice for volatile materials such as odorants. The value of gas chromatography was quickly recognized and this technique has undergone enormous progress, e.g., through the introduction of capillary columns [7] and coupling of this separation tool to identification systems such as mass spectrometry and infrared spectroscopy. Extensive use of these and other analytical procedures have since allowed the identification of about 8000 volatile compounds in food materials [8]. Parallel to investigations into foods this method was also used to analyze many odorant extracts from materials such as flowers, leaves, and other natural sources used historically as fragrance materials. Development in synthetic procedures allowed economical syntheses of these identified compounds which can be used as such or as molecular models (lead compounds) for the synthesis of other not naturally occurring odorants.

1.4. Odor Descriptors, Odor Thresholds, Odor Value

Odors can be measured and described qualitatively and quantitatively, but contrary to the stimuli that elicit our other senses (i.e., sight, hearing, touch, temperature) no physical analytical method exist for odor measurement.

1.4.1. Qualitative Measurements

Qualitative measurements are restricted to verbal descriptions of the odor impression. First approaches to classify odors by their descriptors were initiated by HARPER, BATE SMITH, and LAND [9]. Their general conclusion is that the more complex the odor perception the more impossible becomes an exact odor description. A more detailed analysis into description of odors and thus their qualitative measurement has been initiated by KASTNER [10], who distinguishes three main descriptor categories, i.e., general descriptive terms, special descriptive terms, and precise descriptive terms, in which the first one refers to adjectives like attractive, good, bad, stinky, rough, etc.; the second category comprises explications like green, herbaceous, flowery, earthy; and the third one uses terms like sulfury, ambery, sweaty, etc.

1.4.2. Quantitative Measurements

1.4.2.1. Odor Threshold

Odor strength can be described by its odor threshold. Generally, two different thresholds are used: (1) the *detection threshold*, which is defined as the lowest detectable concentration of a compound versus the pure solvent and (2) the *recognition threshold*, which is the lowest concentration that allows an identification of the odor impression of a compound. Both values are strongly dependent on the solvent system [11].

Thresholds measured in air are generally much lower than those measured in water. A compilation of about 2000 thresholds in water

and in air document the enormous differences that can occur [12].

Thresholds in air can be measured with commercial olfactometers or by standardized smelling from a gas chromatograph as described in [13], whereas thresholds in water and other liquid solvents are determined by the so-called multiple pair test [14], in which the panel members have to decide which of the bottles contain the compound in question. The concentrations are generally presented in a geometrical line. The threshold is defined as the concentration that is correctly identified by 50 % of a panel consisting of a statistically relevant number of testers [15].

1.4.2.2. Odor Value

The quantitative contribution of a compound to the total odor impression can be described by its odor value. This term has been introduced by Rothe et al. [16] and is defined as the concentration of a compound in a given mixture divided by the odor threshold of this compound, i.e., the higher the concentration and the lower the threshold the more the compound contributes to the overall odor impression.

1.5. Regulations and Labeling Requirements

1.5.1. Flavors

Different legislative situations for definition and labeling of flavor active materials exist: The Americas base their systems on the United States Code of Federal Regulations, specifically CFR 101.22, which describes as *artificial flavor* or *artificial flavoring* any substance that imparts flavor, which is not derived from a spice, fruit or fruit juice, vegetable or vegetable juice, edible yeast, herb, bark, bud, root, leaf or similar plant material, meat, fish, poultry, eggs, dairy products, or fermentation products thereof [16]. *Natural flavor* or *natural flavoring* means the essential oil, oleoresin, essence or extractive, protein hydrolysate, distillate, or any product of roasting, heating or enzymolysis, which contains the flavoring constituents derived from a spice, fruit or fruit juice, vegetable or vegetable juice, edible yeast, herb, bark, bud, root, leaf or similar plant material, meat, seafood, poultry, eggs, dairy products, or fermentation products thereof, whose significant function in food is flavoring rather than nutritional [17]. In Europe, these regulations are defined in the "EU Flavouring Directive 88/388 EEC". The term flavoring is restricted to flavoring substances, flavoring preparations, process flavorings, smoke flavorings, or mixtures thereof. A flavoring substance is a defined chemical substance with flavoring properties which is obtained: (i) by appropriate physical processes (including distillation and solvent extraction) or enzymatic or microbiological processes from material of vegetable or animal origin either in the raw state or after processing for human consumption by traditional food-preparation processes (including drying, torrefaction, and fermentation), (ii) by chemical synthesis or isolated by chemical processes and which is chemically identical to a substance naturally present in material of vegetable or animal origin as described in (i), (iii) by chemical synthesis but which is not chemically identical to a substance naturally present in material of vegetable or animal origin. "Process flavoring" means a product which is obtained according to good manufacturing practices by heating to a temperature not exceeding 180 °C for a period not exceeding 15 min from a mixture of ingredients not necessarily themselves having flavoring properties in which at least one contains nitrogen (amino) and another is a reducing sugar. "Smoke flavoring" means a smoke extract used in traditional foodstuffs smoking processes [18].

1.5.2. Fragrances

For fragrances no differentiation is made between natural, nature-identical, and artificial substances. Many compounds used in fragrances are components of natural origin, e.g., constituents of essential oils, resins, and, to a much lesser extent, of animal secretions. In addition many chemicals are used in fragrances, whose molecular structures are not found to occur in nature but their fragrance characteristics mimic those of natural products. For use in fragrance components, these chemicals have to comply with the national legal requirements. In addition they

have to pass the so-called IFRA tests for (see Chap. 6):

Acute toxicity
Skin irritation
Skin sensitization
Phototoxicity and photosensitization

For those products (e.g., fragrance chemicals, essential oils, resinoids) for which IFRA has edited use recommendations this is mentioned by 'IFRA recommendation'. If IFRA suggests a maximum use level then one will find the remark 'limiting IFRA recommendation'. In those cases one may refer to the IFRA publications for further information.

2. Single Fragrance and Flavor Compounds

Fragrance and flavor compounds of commercial interest are arranged according to the Beilstein system of functional groups, not according to their organoleptic properties, since relationships between odor and structure are difficult to establish. However, the Beilstein system has been abandoned in a few cases for practical reasons.

In each class of parent compounds, hydrocarbons and oxygen-containing compounds are described first. Nitrogen- and sulfur-containing compounds are treated at the end of each of these sections under the heading Miscellaneous Compounds. Aliphatic compounds are discussed in Section 2.1, followed by the terpenes. The terpenes constitute a very important group of compounds and are subdivided into acyclic terpenes (Section 2.2) and cyclic terpenes (Section 2.3). Nonterpenoid cycloaliphatics are described in Section 2.4. Aromatic compounds are discussed in Section 2.5. Phenols and phenol derivatives are described under a separate heading (Section 2.6) on account of their biogenetic and odor relationships. Methylenedioxyphenyl derivatives are also described under this heading for the same reason even though, systematically, they belong to the oxygen-containing heterocycles (Section 2.7). Compounds that are only produced in small quantities, but which are important due to their high odor intensity, are mentioned but not described in detail.

2.1. Aliphatic Compounds

The acyclic terpenes are discussed separately in Section 2.2. Some of the cycloaliphatic fragrance and flavor compounds are structurally related to the cyclic terpenes and are, therefore, discussed in Section 2.4 after the cyclic terpenes.

2.1.1. Hydrocarbons

Saturated and unsaturated aliphatic hydrocarbons with straight as well as branched chains occur abundantly in natural foodstuffs, but they contribute to the odor and taste only to a limited extent. The highly unsaturated hydrocarbons 1,3-*trans*-5-*cis*-undecatriene [*51447-08-6*] and 1,3-*trans*-5-*trans*-undecatriene [*19883-29-5*], however, contribute to the odor of galbanum oil [19].

2.1.2. Alcohols (→ Alcohols, Aliphatic; → Fatty Alcohols)

Free and esterified saturated primary alcohols occur widely in nature, e.g., in fruit. Since their odor is relatively weak, their use as components in fragrance compositions is limited. Their use in aroma compositions, especially for fruit flavors, is by far more important (e.g., straight-chain $C_4 - C_{10}$ alcohols, isoamyl alcohol). Unsaturated alcohols are most important (e.g., leaf alcohol with its intensely green odor) and may impart characteristic notes to compositions.

Naturally occurring fatty alcohols used in the fragrance industry are produced principally by reduction of the methyl esters of the corresponding carboxylic acids, which are obtained by transesterification of natural fats and oils with methanol. Industrial reduction processes include catalytic hydrogenation in the presence of copper–chromium oxide catalysts (Adkins catalysts) and reduction with sodium (Bouveault–Blanc reduction); for details, see → Alcohols, Aliphatic, Chap. 2.3.3., → Fatty Alcohols, Chap. 2.3., → Fatty Alcohols, Chap. 2.4. Unsaturated alcohols can also be prepared by the latter method. Alcohols are starting materials for aldehydes and esters.

3-Octanol [*589-98-0*], $CH_3(CH_2)_4CH(OH)CH_2CH_3$, $C_8H_{18}O$, M_r 130.23, *bp* (97.6 kPa) 176 – 176.5 °C, d_4^{20} 0.8264, n_D^{20} 1.4252, may occur in its optically active form. It is a colorless liquid that has a mushroomy-earthy odor and occurs in mushrooms. 3-Octanol can be obtained by hydrogenation of 3-octanone; it is used in lavender compositions and for imparting mushroom-like odors.

2,6-Dimethyl-2-heptanol [*13254-34-7*], $C_9H_{20}O$, M_r 144.26, *bp* (101.3 kPa) 170 – 172 °C, d_4^{20} 0.8085, n_D^{20} 1.4248, which has not yet been found in nature, is a colorless liquid with a delicate, flowery odor reminiscent of fresias. It is synthesized from 2-methyl-2-hepten-6-one and methylmagnesium chloride by a Grignard reaction, followed by hydrogenation, and is used in flowery perfume compositions.

Trade Names. Dimetol (Givaudan Roure), Freesiol (Haarmann & Reimer).

***trans*-2-Hexen-1-ol** [*928-95-0*], $CH_3CH_2CH_2CH{=}CHCH_2OH$, $C_6H_{12}O$, M_r 100.16, *bp* (101.3 kPa) 155 °C, d_4^{20} 0.8459, n_D^{20} 1.4382, occurs in many fruits and has a fruity, green odor, which is sweeter than that of the isomeric *cis*-3-hexen-1-ol and is, therefore, preferred in aroma compositions.

***cis*-3-Hexen-1-ol** [*928-96-1*], leaf alcohol, $CH_3CH_2CH{=}CHCH_2CH_2OH$, $C_6H_{12}O$, M_r 100.16, *bp* (101.3 kPa) 156 – 157 °C, d_4^{20} 0.8495, n_D^{20} 1.4384, is a colorless liquid with the characteristic odor of freshly cut grass. *Robinia pseudacacia* and mulberry leaf oil contain up to 50 % leaf alcohol, and green tea up to 30 %. Small quantities occur in the green parts of nearly all plants.

A stereospecific synthesis for *cis*-3-hexen-1-ol starts with the ethylation of sodium acetylide to 1-butyne, which is reacted with ethylene oxide to give 3-hexyn-1-ol. Selective hydrogenation of the triple bond in the presence of palladium catalysts yields *cis*-3-hexen-1-ol. Leaf alcohol is used to obtain natural green top notes in perfumes and flavors. In addition, it is the starting material for the synthesis of 2-*trans*-6-*cis*-nonadien-1-ol and 2-*trans*-6-*cis*-nonadien-1-al.

1-Octen-3-ol [*3391-86-4*], $CH_3(CH_2)_4CH(OH)CH{=}CH_2$, $C_8H_{16}O$, M_r 128.21, *bp* (94.6 kPa) 175 – 175.2 °C, d_4^{20} 0.8383, n_D^{20} 1.4378, may occur in the optically active form. It is found, for example, in lavender oil and is a steam-volatile component of mushrooms. 1-Octen-3-ol is a liquid with an intense mushroom, forest-earthy odor that can be prepared by a Grignard reaction from vinylmagnesium bromide and hexanal. It is used in lavender compositions and in mushroom aromas.
Trade Name. Matsutake alcohol (Takasago).

9-Decen-1-ol [*13019-22-2*], $CH_2{=}CH(CH_2)_6CH_2OH$, $C_9H_{18}O$, M_r 142.24, *bp* (270 Pa) 85 – 86 °C, n_D^{20} 1.4480, has been identified as a trace constituent of cognac. It is a colorless liquid with a fresh, dewy, rose note that can be prepared by partial dehydration of 1,10-decanediol. It is used in rosy-floral soap perfumes.
Trade Name. Rosalva (IFF).

10-Undecen-1-ol [*112-43-6*], $CH_2{=}CH(CH_2)_8CH_2OH$, $C_{11}H_{22}O$, M_r 170.29, *bp* (2.1 kPa) 133 °C, d_4^{20} 0.8460, n_D^{20} 1.4500, has not yet been found in nature and is a colorless liquid with a fatty-green, slightly citrus-like odor. It can be synthesized from 10-undecylenic acid and is used to give flower perfumes a fresh note.

2-*trans*-6-*cis*-Nonadien-1-ol [*28069-72-9*], $CH_3CH_2CH{=}CHCH_2CH_2CH{=}CHCH_2OH$, $C_9H_{16}O$, violet leaf alcohol, M_r 140.22, *bp* (1.5 kPa) 96 – 100 °C, d_4^{10} 0.8622, n_D^{20} 1.4740, occurs, for example, in cucumber oil, violet leaf oil, and violet blossom oil. It is a colorless liquid with an intense, heavy-fatty, green odor, reminiscent of violet leaves. The starting material for the synthesis of 2-*trans*-6-*cis*-nonadien-1-ol is *cis*-3-hexen-1-ol, which is converted via its halide into the corresponding Grignard reagent. The Grignard reagent is reacted with acrolein to give 1,6-nonadien-3-ol, which is converted

into 2-*trans*-6-*cis*-nonadien-1-ol by allylic rearrangement.

Nonadienol is a powerful fragrance substance. It is used in fine fragrances to create refined violet odors and to impart interesting notes to other blossom compositions. In aroma compositions it is used for fresh-green cucumber notes.

2.1.3. Aldehydes and Acetals

(→ Aldehydes, Aliphatic and Araliphatic)

Aliphatic aldehydes are among the most important components used in perfumery. Although the lower fatty aldehydes $C_2 - C_7$ occur widely in nature, they are – with the exception of hexanal – seldom used in fragrance compositions. The lower aldehydes (e.g., acetaldehyde, isobutyraldehyde, isovaleraldehyde, and 2-methylbutyraldehyde) impart fruity and roast characters to flavor compositions. Fatty aldehydes C_8–C_{13}, however, are used, singly or in combination, in nearly all perfume types and also in aromas. Their odor becomes weaker with increasing molecular mass, so that aldehydes $> C_{13}$ are not important as perfume ingredients.

In addition to the straight-chain saturated aldehydes, a number of branched-chain and unsaturated aliphatic aldehydes are important as fragrance and flavoring materials. The double unsaturated 2-*trans*-6-*cis*-nonadienal [*557-48-2*], "violet leaf aldehyde" (the dominant component of cucumber aroma), is one of the most potent fragrance and flavoring substances; it is, therefore, only used in very small amounts.

Acetals derived from aliphatic aldehydes have odor characteristics that resemble those of the aldehydes but are less pronounced. These acetals contribute to the aroma of alcoholic beverages, but can rarely be used in flavoring compositions because they are not sufficiently stable. Since they are resistant to alkali, a number of them (e.g., heptanal dimethyl acetal and octanal dimethyl acetal) are occasionally incorporated into soap perfumes.

Fatty aldehydes are generally produced by dehydrogenation of alcohols in the presence of suitable catalysts (see → Aldehydes, Aliphatic and Araliphatic, Chap. 2.3.). The alcohols are often cheap and available in good purity. Aldehyde synthesis via the oxo process is less suitable since the resultant products are often not pure enough for flavor and perfume purposes. Specific syntheses for the branched-chain and unsaturated aldehydes that are important in perfumery and flavoring techniques are described under the individual compounds.

Hexanal [*66-25-1*], caproaldehyde, $CH_3(CH_2)_4CHO$, $C_6H_{12}O$, M_r 100.16, *bp* (101.3 kPa) 128 °C, d_4^{20} 0.8139, n_D^{20} 1.4039, occurs, for example, in apple and strawberry aromas as well as in orange and lemon oil. It is a colorless liquid with a fatty-green odor and in low concentration is reminiscent of unripe fruit.

Hexanal is used in fruit flavors and, when highly diluted, in perfumery for obtaining fruity notes.

Octanal [*124-13-0*], caprylaldehyde, $CH_3(CH_2)_6CHO$, $C_8H_{16}O$, M_r 128.21, *bp* (101.3 kPa) 171 °C, d_4^{20} 0.8211, n_D^{20} 1.4217, occurs in several citrus oils, e.g., orange oil. It is a colorless liquid with a pungent odor, which becomes citrus-like on dilution. Octanal is used in perfumery in low concentrations, in eaux de cologne, and in artificial citrus oils.

Nonanal [*124-19-6*], pelargonaldehyde, $CH_3(CH_2)_7CHO$, $C_9H_{18}O$, M_r 142.24, *bp* (101.3 kPa) 190 – 192 °C, d_4^{20} 0.8264, n_D^{20} 1.4273, occurs in citrus and rose oils. It is a colorless liquid with a fatty-roselike odor and is used in floral compositions, particularly those with rose characteristics.

Decanal [*112-31-2*], capraldehyde, caprinaldehyde, $CH_3(CH_2)_8CHO$, $C_{10}H_{20}O$, M_r 156.27, *bp* (101.3 kPa) 208 – 209 °C, d_4^{20} 0.8259, n_D^{20} 1.4287, is a component of many essential oils (e.g., neroli oil) and various citrus peel oils. It is a colorless liquid with a strong odor, reminiscent of orange peel, that changes to a fresh citrus odor when diluted. Decanal is used in low concentrations in blossom fragrances (especially to create citrus nuances) and in the production of artificial citrus oils.

Undecanal [*112-44-7*], $CH_3(CH_2)_9CHO$, $C_{11}H_{22}O$, M_r 170.29, *bp* (2.4 kPa) 117 °C, d_4^{20} 0.8250, n_D^{20} 1.4325, occurs in citrus oils. It is a colorless liquid with a flowery-waxy odor that

has aspects of freshness. Undecanal is the prototype of the perfumery aldehydes and is widely used in perfume compositions for imparting an "aldehydic note".

Dodecanal [*112-54-9*], lauraldehyde, lauric aldehyde, $CH_3(CH_2)_{10}CHO$, $C_{12}H_{24}O$, M_r 184.32, *bp* (13.3 kPa) 185 °C, d_4^{20} 0.8350, n_D^{20} 1.4350, is a colorless liquid with a waxy odor; in high dilution it is reminiscent of violets. Dodecanal occurs in several citrus oils and has been found in small amounts in essential oils obtained from several *Pinus* species. It is used in perfumery in conifer fragrances with fatty-waxy notes, but also in many other odor types. It is added to aroma compositions to obtain citrus notes.

Tridecanal [*10486-19-8*], $CH_3(CH_2)_{11}CHO$, $C_{13}H_{26}O$, M_r 198.34, *bp* (1.3 kPa) 128 °C, d_4^{20} 0.8358, n_D^{18} 1.4384, occurs in lemon oil and has been identified as a volatile constituent of cucumber. It is a colorless liquid having a fatty-waxy, slightly citrus-like odor. Addition of tridecanal to fragrance compositions imparts fresh nuances in the top note as well as in the dry out.

2-Methyldecanal [*19009-56-4*], methyloctylacetaldehyde, $CH_3(CH_2)_7CH(CH_3)CHO$, $C_{11}H_{22}O$, M_r 170.29, *bp* (98.8 kPa) 119–120 °C, d_4^{20} 0.8946, n_D^{20} 1.4205, is not reported to have been found in nature. It is a colorless liquid with an aldehydic, citrus-peel-like, waxy-green odor. 2-Methyldecanal is obtained as a byproduct in the manufacture of 2-methylundecanal by hydroformylation of 1-decene. It is used in perfumery to refresh green and citrus nuances.

2-Methylundecanal [*110-41-8*], methylnonylacetaldehyde, $CH_3(CH_2)_8CH(CH_3)CHO$, $C_{12}H_{24}O$, M_r 184.32, *bp* (1.3 kPa) 114 °C, d_4^{20} 0.8303, n_D^{20} 1.4321, has not yet been found in nature. It is a colorless liquid, with an odor markedly different from that of the isomeric dodecanal. It has a fatty odor with incense and ambergris notes.

2-Methylundecanal is produced by two routes:

1) Methyl nonyl ketone is converted into its glycidate by reaction with an alkyl chloroacetate. Saponification of the glycidate, followed by decarboxylation, yields 2-methylundecanal.
2) The second synthesis is based on the conversion of undecanal into 2-methyleneundecanal by reaction with formaldehyde in the presence of catalytic amounts of amines [20]. Hydrogenation of 2-methyleneundecanal yields methylnonylacetaldehyde. A convenient process starts from 1-decene: hydroformylation gives a mixture consisting mainly of undecanal and 2-methyldecanal. Reaction of the crude product with formaldehyde in the presence of dibutylamine yields a mixture containing over 50 % 2-methyleneundecanal. After hydrogenation of the double bond, pure 2-methylundecanal is separated from byproducts by fractional distillation [21].

In comparison with other fatty aldehydes, 2-methylundecanal is used in perfumery in rather large amounts to impart conifer notes, particularly fir impressions, but frequently also in phantasy compositions.

***trans*-2-Hexenal** [*6728-26-3*], leaf aldehyde, $CH_3CH_2CH_2CH{=}CHCHO$, $C_6H_{10}O$, M_r 98.14, *bp* (101.3 kPa) 146–147 °C, d_4^{20} 0.8491, n_D^{20} 1.4480, is the simplest straight-chain unsaturated aldehyde of interest for perfumes and

flavors. It occurs in essential oils obtained from green leaves of many plants. *trans*-2-Hexenal is a colorless, sharp, herbal-green smelling liquid with a slight acrolein-like pungency. Upon dilution, however, it smells pleasantly green and apple-like. The aldehyde can be synthesized by reacting butanal with vinyl ethyl ether in the presence of boron trifluoride, followed by hydrolysis of the reaction product with dilute sulfuric acid [22].

trans-2-Hexenal has an intense odor and is used in perfumes to obtain a green-leaf note, and in fruit flavors for green nuances (limiting IFRA recommendation). (See Sec. 1.5.2 Fragrances).

***cis*-4-Heptenal** [*6728-31-0*], $CH_3CH_2CH{=}CHCH_2CH_2CHO$, $C_7H_{12}O$, M_r 112.17, *bp* (1.33 kPa) 41 °C, n_D^{20} 1.4343, is a widespread volatile trace constituent of food flavors. It is a colorless, oily liquid with a powerful, fatty, somewhat fishy and, in high dilution, creamy odor. It can be prepared from 1-butyne (via lithium 1-butynide) and acrolein (which is converted into 2-bromopropionaldehyde dimethyl acetal). The resulting 4-heptynal dimethyl acetal is cleaved and the triple bond is hydrogenated catalytically to give *cis*-4-heptenal [23].

cis-4-Heptenal is used in cream, butter, and fat flavors.

10-Undecenal [*112-45-8*], $CH_2{=}CH(CH_2)_8CHO$, $C_{11}H_{20}O$, M_r 168.28, *bp* (400 Pa) 103 °C, d_4^{20} 0.8495, n_D^{20} 1.4459, has not yet been found in nature. It is a colorless liquid with a fatty-green, slightly metallic, heavy-flowery odor. The aldehyde can be synthesized from undecylenic acid, for example, by hydrogenation of the acid chloride (Rosenmund reduction) or by reaction with formic acid in the vapor phase in the presence of titanium dioxide. In perfumery, 10-undecenal is one of the aldehydes essential for creating the "aldehydic note".

2.1.4. Ketones (→ Ketones)

Aliphatic monoketones are of minor importance as fragrance and aroma substances. 2-Alkanones (C_3-C_{15}) have been found in the volatile fractions of many fruits and foods, but they do not contribute significantly to their aroma. An exception are the odd-numbered methyl ketones C_7, C_9, C_{11}, which possess a characteristic nutty note; they are used, e.g., in cheese flavor compositions. In perfumery, aliphatic ketones are used for accentuation, e.g., 3-octanone [*106-68-3*] for lavender notes. The hydroxyketone acetoin and the diketone 2,3-butanedione are commercially important aroma substances.

Acetoin [*52217-02-4*], 3-hydroxy-2-butanone, $CH_3COCH(OH)CH_3$, $C_4H_8O_2$, M_r 88.11, *bp* (101.3 kPa) 148 °C, d_4^{20} 1.0058, n_D^{20} 1.4171, has a pleasant buttery odor and both of its optical isomers occur widely in nature. It is synthesized by partial oxidation of 2,3-butanediol and is obtained as a byproduct in the fermentation of molasses. It is used for flavoring margarine.

2,3-Butanedione [*431-03-8*], diacetyl, $CH_3COCOCH_3$, $C_4H_6O_2$, M_r 86.09, *bp* 88 °C (101.3 kPa), d_4^{20} 0.9831, n_D^{20} 1.3950, is a constituent of many fruit and food aromas and well-known as a constituent of butter. Many methods are known for its manufacture, e.g., dehydrogenation of 2,3-butanediol with a copper chromite catalyst [24]. It is used mainly in aromas for butter and roast notes. Large quantities are used for flavoring margarine; small amounts are used in perfumes.

2.1.5. Acids and Esters (→ Carboxylic Acids, Aliphatic; → Esters Organic)

Straight-chain, saturated aliphatic acids are found in many essential oils and foods. These acids contribute to aromas, but are not important as fragrance substances. In flavor compositions, aliphatic acids up to C_{10} are used to accentuate certain aroma characteristics (C_3-C_8 for fruity notes; C_4, C_6-C_{12} for cheese flavors). However, straight-chain and some branched-chain

aliphatic acids are of considerable importance as starting materials in the manufacture of esters, many of which are valuable fragrance and flavor materials. Aliphatic esters contribute to the aroma of nearly all fruits and many foods. Some are responsible for a particular fruit aroma, or for the smell of a particular flower; however, many of these esters possess a nonspecific fruity odor.

Most of the esters used are acetates and ethanol is the most common alcohol component. In nature, most esters are derived from alcohols and acids with an even number of carbon atoms. In addition to straight-chain saturated compounds, branched-chain compounds such as isoamyl esters and unsaturated compounds such as hexenyl esters are important.

Although the odor of aliphatic esters with a small number of carbon atoms is strictly fruity, it changes to fatty-soapy and even metallic as the number of carbon atoms increases.

Esters are usually prepared by esterification of carboxylic acids with alcohols. Industrial procedures depend on the physical properties of the esters concerned (see → Esters, Organic).

In perfumery, acetates are the most important aliphatic esters; formates do not keep well. Animal and fatty notes become more pronounced in esters of higher fatty acids. Acetates of alcohols up to C_6 are used principally for fruity notes, whereas the acetates of C_8, C_{10}, and C_{12} alcohols are employed for blossom fragrances and for flower notes in general. Lauryl acetate in particular is also used for conifer notes.

In flavor compositions, aliphatic esters are preferred for artificial fruit aromas; as in nature, acetates and ethyl esters prevail.

Ethyl formate [*109-94-4*], $HCOOCH_2CH_3$, $C_3H_6O_2$, M_r 74.08, *bp* (101.3 kPa) 54.5 °C, d_4^{20} 0.9168, n_D^{20} 1.3598, occurs widely in fruits. It is a liquid with a slightly pungent, fruity, ethereal odor and is used in fruit flavors.

***cis*-3-Hexenyl formate** [*33467-73-1*], $HCOO(CH_2)_2CH{=}CHCH_2CH_3$, $C_7H_{12}O_2$, M_r 128.17, *bp* (101.3 kPa) 155 °C, d_4^{20} 0.9121, n_D^{20} 1.4270, has been identified in tea. It possesses a green-fruity odor and is used in perfumery and flavor compositions to impart fruity green notes.

Ethyl acetate [*141-78-6*], $CH_3COOCH_2CH_3$, $C_4H_8O_2$, M_r 88.11, *bp* (101.3 kPa) 77.1 °C, d_4^{20} 0.9003, n_D^{20} 1.3723, is a fruity smelling liquid with a brandy note and is the most common ester in fruits. It is used in fruit and brandy flavors.

Butyl acetate [*123-86-4*], $CH_3COO(CH_2)_3CH_3$, $C_6H_{12}O_2$, M_r 116.16, *bp* (101.3 kPa) 126.5 °C, d_4^{20} 0.9003, n_D^{20} 1.3942, is a liquid with a strong fruity odor. It occurs in many fruits and is a constituent of apple aromas.

Isoamyl acetate [*123-92-2*], $CH_3COO(CH_2)_2CH(CH_3)_2$, $C_7H_{14}O_2$, M_r 130.19, *bp* (101.3 kPa) 142.5 °C, d_4^{20} 0.8730, n_D^{20} 1.4006, is a strongly fruity smelling liquid and has been identified in many fruit aromas. It is the main component of banana aroma and is, therefore, also used in banana flavors.

Hexyl acetate [*142-92-7*], $CH_3COO(CH_2)_5CH_3$, $C_8H_{16}O_2$, M_r 144.21, *bp* (101.3 kPa) 171.5 °C, d_4^{20} 0.8730, n_D^{20} 1.4092, is a liquid with a sweet-fruity, pearlike odor. It is present in a number of fruits and alcoholic beverages, and is used in fruit aroma compositions.

3,5,5-Trimethylhexyl acetate [*58430-94-7*], $CH_3COO(CH_2)_2CH(CH_3)CH_2C(CH_3)_3$, isononyl acetate, $C_{11}H_{22}O_2$, M_r 186.29, does not occur in nature. Commercial isononyl acetate contains small amounts of byproducts. It is a colorless liquid with a woody-fruity odor and is prepared from diisobutene by the oxo synthesis, followed by hydrogenation to the alcohol and acetylation. It is used in household perfumery.

***trans*-2-Hexenyl acetate** [*2497-18-9*], $CH_3COOCH_2CH{=}CH(CH_2)_2CH_3$, $C_8H_{14}O_2$, M_r 142.20, *bp* (2.1 kPa) 67 – 68 °C, d_4^{20} 0.8975, n_D^{20} 1.4277, occurs in many fruits and in some essential oils, e.g., peppermint. It is a fresh-fruity, slightly green smelling liquid and is used in fruit flavors.

***cis*-3-Hexenyl acetate** [*3681-71-8*], $CH_3COO(CH_2)_2CH{=}CHCH_2CH_3$, $C_8H_{14}O_2$, M_r 142.20, *bp* (1.6 kPa) 66 °C, has been identified in many fruit aromas and green tea. It is a prototype for green odors and is often used in combination with *cis*-3-hexenol.

Ethyl propionate [*105-37-3*], $CH_3CH_2COOCH_2CH_3$, $C_5H_{10}O_2$, M_r 102.13, *bp* (101.3 kPa) 99 °C, d_4^{20} 0.8896, n_D^{20} 1.3839, is found in many fruits and alcoholic beverages. It has a fruity odor reminiscent of rum and is used in flavor compositions for creating both fruity and rum notes.

Ethyl butyrate [*105-54-4*], $CH_3(CH_2)_2COOCH_2CH_3$, $C_6H_{12}O_2$, M_r 116.16, *bp* (101.3 kPa) 121 – 122 °C, d_4^{20} 0.8785, n_D^{20} 1.4000, occurs in fruits and alcoholic beverages, but also in other foods such as cheese. It has a fruity odor, reminiscent of pineapples. Large amounts are used in perfume and in flavor compositions.

Butyl butyrate [*109-21-7*], $CH_3(CH_2)_2COOCH_2(CH_2)_2CH_3$, $C_8H_{16}O_2$, M_r 144.21, *bp* (101.3 kPa) 166 °C, d_4^{20} 0.8709, n_D^{20} 1.4075, is a liquid with a sweet-fruity odor. It is a volatile constituent of many fruits and honey and is used in fruit flavor compositions.

Isoamyl butyrate [*106-27-4*], $CH_3(CH_2)_2COO(CH_2)_2CH(CH_3)_2$, $C_9H_{18}O_2$, M_r 158.23, *bp* (101.3 kPa) 178.5 °C, d_4^{20} 0.8651, n_D^{20} 1.4106, is a liquid with strongly fruity odor that occurs, e.g., in banana. It is used mainly in fruit flavors.

Hexyl butyrate [*2639-63-6*], $CH_3(CH_2)_2COO(CH_2)_5CH_3$, $C_{10}H_{20}O_2$, M_r 172.27, *bp* (101.3 kPa) 208 °C, d_4^{20} 0.8652, n_D^{20} 1.3920, is a liquid with a powerful fruity odor. It has been identified in a number of fruits and berries and is an important constituent of fruit flavor compositions.

***cis*-3-Hexenyl isobutyrate** [*41519-23-7*], $(CH_3)_2CHCOO(CH_2)_2CH{=}CHCH_2CH_3$, $C_{10}H_{18}O_2$, M_r 170.25 is found in spearmint oil. It smells fruity-green and is used in perfumery to create freshness in blossom compositions.

Ethyl isovalerate [*108-64-5*], $(CH_3)_2CHCH_2COOCH_2CH_3$, $C_7H_{14}O_2$, M_r 130.19, *bp* (101.3 kPa) 134.7 °C, d_4^{20} 0.8656, n_D^{20} 1.3962, is a colorless liquid with a fruity odor reminiscent of blueberries. It occurs in fruits, vegetables, and alcoholic beverages. It is used in fruity aroma compositions.

Ethyl 2-methylbutyrate [*7452-79-1*], $CH_3CH_2CH(CH_3)COOCH_2CH_3$, $C_7H_{14}O_2$, M_r 130.19, *bp* (101.3 kPa) 131 – 132 °C, d_4^{25} 0.8689, n_D^{20} 1.3964, is a liquid with a green-fruity odor reminiscent of apples. It is found, for example, in citrus fruits and wild berries and is used in fruit flavor compositions.

Ethyl hexanoate [*123-66-0*], ethyl caproate, $CH_3(CH_2)_4COOCH_2CH_3$, $C_8H_{16}O_2$, M_r 144.21, *bp* (101.3 kPa) 168 °C, d_4^{20} 0.8710, n_D^{20} 1.4073, is a colorless liquid with a strong fruity odor, reminiscent of pineapples. It occurs in many fruits and is used in small amounts for flowery-fruity notes in perfume compositions and in larger quantities in fruit flavors.

2-Propenyl hexanoate [*123-68-2*], allyl caproate, $CH_3(CH_2)_4COOCH_2CH{=}CH_2$, $C_9H_{16}O_2$, M_r 156.22, *bp* (2 kPa) 75 – 76 °C, d_4^{20} 0.8869, n_D^{20} 1.4243, and also to occurs in nature. It has a typical pineapple odor and is used in, for example, artificial pineapple flavors. (Limiting IFRA recommendation) (see Sec. 1.5.2 Fragrances).

Ethyl heptanoate [*106-30-9*], ethyl enanthate, $CH_3(CH_2)_5COOCH_2CH_3$, $C_9H_{18}O_2$, M_r 158.24, *bp* (101.3 kPa) 187 – 188 °C, d_4^{20} 0.8680, n_D^{20} 1.4120, is a colorless liquid with a fruity odor reminiscent of cognac. It is found in fruits and alcoholic beverages and is used in appropriate aroma compositions.

2-Propenyl heptanoate [*142-19-8*], allyl enanthate, $CH_3(CH_2)_5COOCH_2CH{=}CH_2$, $C_{10}H_{18}O_2$, M_r 170.25, *bp* (101.3 kPa) 210 °C, d_4^{20} 0.8927, n_D^{20} 1.4290, has not yet been found in nature. It is used in perfume compositions for apple-like (pineapple) notes. (Llimiting IFRA recommendation) (see Sec. 1.5.2 Fragrances).

Ethyl octanoate [*106-32-1*], ethyl caprylate, $CH_3(CH_2)_6COOCH_2CH_3$, $C_{10}H_{20}O_2$, M_r 172.27, *bp* (101.3 kPa) 208 °C, d_4^{20} 0.8693, n_D^{20} 1.4178, is a liquid with a fruity-flowery odor. It occurs in many fruits and alcoholic beverages and is used in fruit flavors.

Ethyl 2-*trans*-4-*cis*-decadienoate [*3025-30-7*], $CH_3(CH_2)_4CH{=}CHCH{=}CHCOOCH_2CH_3$, $C_{12}H_{20}O_2$, M_r 196.29, *bp* (6 kPa) 70–72 °C, has been identified in pears and has the typical aroma of Williams pears. Synthesis of ethyl 2-*trans*-4-*cis*-decadienoate starts from *cis*-1-heptenyl bromide, which is converted into a 1-heptenyllithium cuprate complex with lithium and copper iodide. Reaction with ethyl propiolate yields a mixture of 95 % ethyl 2-*trans*-4-*cis*- and 5 % ethyl 2-*trans*-4-*trans*-decadienoate. Pure ethyl 2-*trans*-4-*cis*-decadienoate is obtained by fractional distillation [25].

Methyl 2-octynoate [*111-12-6*], $CH_3(CH_2)_4C{\equiv}CCOOCH_3$, $C_9H_{14}O_2$, M_r 154.21, *bp* (1.3 kPa) 94 °C, d_4^{20} 0.9320, n_D^{20} 1.4464. Limiting IFRA recommendation.

Methyl 2-nonynoate [*111-80-8*], $CH_3(CH_2)_5C{\equiv}CCOOCH_3$, $C_{10}H_{16}O_2$, M_r 168.24, *bp* (2.7 kPa) 121 °C, d_4^{20} 0.9162, n_D^{25} 1.4395. Both methyl 2-nonynoate and methyl 2-octynoate have a triple bond and are liquids with a fatty, violet-leaf-like odor. They are used in perfume compositions. Limiting IFRA recommendation.

2.1.6. Miscellaneous Compounds

A number of volatile aliphatic compounds that contain nitrogen or sulfur atoms are important aroma constituents. Alkyl thiols, dialkyl sulfides and disulfides, and alkyl thiocyanates belong to this group. They occur widely in foods and spices and determine the odor of, for example, onions, garlic, and mustard. Because of their potent smell, they are used in high dilution and are often produced only in small quantities. The same is true for 3-methylthiohexanol [*51755-66-9*], $CH_3(CH_2)_2CH(SCH_3)CH_2CH_2OH$, a volatile constituent of passion fruits. Allyl isothiocyanate, however, is an exception in that it is produced in large quantities.

Allyl isothiocyanate [*57-06-7*], allyl mustard oil, $CH_2{=}CHCH_2N{=}C{=}S$, C_4H_5NS, M_r 99.14, *bp* (101.3 kPa) 152 °C, d_4^{20} 1.0126, is the main component of mustard oil (> 95 %). It is a colorless oil with a typical mustard odor and can be prepared by reacting allyl chloride with alkaline-earth or alkali isothiocyanates [26].

2.2. Acyclic Terpenes

For a general description of terpenes, see → Terpenes.

2.2.1. Hydrocarbons

Acyclic terpene (C_{10}) and sesquiterpene (C_{15}) hydrocarbons find little use in flavor and fragrance compositions. They are relatively unstable and some have a slightly aggressive odor due to their highly unsaturated structure. Myrcene, ocimene, and farnesene, are present in many fruits and essential oils, but find only limited use in perfumery.

Myrcene

Ocimene

β-Farnesene

2.2.2. Alcohols

Acyclic terpene and sesquiterpene alcohols occur in many essential oils. These alcohols were formerly isolated from oils in which they are major components. Currently, large-scale synthesis of terpenoids permits production without the uncertainties associated with isolation from natural sources. However, the odor qualities of synthetic products often differ from those of compounds isolated from natural sources, since the desired natural product often cannot be separated from small amounts of compounds with similar physical properties but different odor quality.

The acyclic terpene alcohols geraniol, linalool, and citronellol are the most important

terpene alcohols used as fragrance and flavor substances. Geraniol and linalool are, in addition to nerol and lavandulol, primary products in terpene biosynthesis. The fully saturated alcohols tetrahydrogeraniol and tetrahydrolinalool are also used in large quantities in fragrance compositions. The fragrance materials myrcenol, identified in lavender oil, and its dihydro and tetrahydro derivatives, which have not yet been found in nature, belong structurally to the terpenes. The sesquiterpene alcohols farnesol and nerolidol are popular materials for perfume compositions.

Geraniol

Nerol

Linalool

Myrcenol

Lavandulol

Citronellol

trans,trans-Farnesol

trans-Nerolidol

Geraniol and nerol are *cis–trans*-isomers. In the rarely occurring lavandulol, the isoprene units are not coupled in the normal head-to-tail manner.

The farnesols and nerolidols are sesquiterpene analogs of geraniol–nerol and linalool. These compounds are formed by extending one of the methyl groups in the 7-position of the corresponding monoterpene with an isoprene unit. Because these compounds have an extra double bond, they also have an additional possibility for *cis–trans*-isomerism. Thus, there are four stereoisomers of farnesol and two of nerolidol.

Geraniol [*106-24-1*], 3,7-dimethyl-*trans*-2,6-octadien-1-ol, $C_{10}H_{18}O$, M_r 154.25, *bp* (101.3 kPa) 230 °C, d_4^{20} 0.8890, n_D^{20} 1.4777, occurs in nearly all terpene-containing essential oils, frequently as an ester. Palmarosa oil contains 70 – 85 % geraniol; geranium oils and rose oils also contain large quantities. Geraniol is a colorless liquid, with a flowery-roselike odor.

Since geraniol is an acyclic, doubly unsaturated alcohol, it can undergo a number of reactions, such as rearrangement and cyclization. Rearrangement in the presence of copper catalysts yields citronellal. In the presence of mineral acids, it cyclizes to form monocyclic terpene hydrocarbons, cyclogeraniol being obtained if the hydroxyl function is protected. Partial hydrogenation leads to citronellol, and complete hydrogenation of the double bonds yields 3,7-dimethyloctan-1-ol (tetrahydrogeraniol). Citral is obtained from geraniol by oxidation (e.g., with chromic acid), or by catalytic dehydrogenation. Geranyl esters are prepared by esterification.

Production. Dehydrogenation of geraniol and nerol is a convenient route for synthesizing citral, which is used in large quantities as an intermediate in the synthesis of vitamin A. Large-scale processes have, therefore, been developed for producing geraniol. Currently, these are far more important than isolation from essential oils. Nevertheless, some geraniol is still isolated from essential oils for perfumery purposes.

1) *Isolation from Essential Oils.* Geraniol is isolated from citronella oils and from palmarosa oil. Fractional distillation of, for example, Java citronella oil (if necessary after saponification of the esters present) yields a fraction containing ca. 60 % geraniol, as well as citronellol and sesquiterpenes.
   A product with a higher geraniol content and slightly different odor quality for use in fine fragrances is obtained by fractionating palmarosa oil after saponification of the geranyl esters.
2) *Synthesis from β-Pinene.* Pyrolysis of β-pinene yields myrcene, which is converted into a mixture of predominantly geranyl,

neryl, and linalyl chloride by addition of hydrogen chloride in the presence of small amounts of catalyst, e.g., copper(I) chloride and an organic quaternary ammonium salt [27]. After removal of the catalyst, the mixture is reacted with sodium acetate in the presence of a nitrogen base (e.g., triethylamine) and converted to geranyl acetate, neryl acetate, and a small amount of linalyl acetate [28]. After saponification and fractional distillation of the resulting alcohols, a fraction is obtained that contains ca. 98 % geraniol.

3) *Synthesis from Linalool.* Recently, a 96 % pure synthetic geraniol prepared by isomerization of linalool has become commercially available. Orthovanadates are used as catalysts, to give a > 90 % yield of a geraniol–nerol mixture [29]. Geraniol of high purity is finally obtained by fractional distillation.
A considerable portion of commercially available geraniol is produced by a modified process: linalool obtained in a purity of ca. 65 % from α-pinene is converted into linalyl borates, which rearrange in the presence of vanadates as catalysts to give geranyl and neryl borates. The alcohols are obtained by hydrolysis of the esters [30].

Uses. Geraniol is one of the most frequently used terpenoid fragrance materials. It can be used in all flowery-roselike compositions and does not discolor soaps. In flavor compositions, geraniol is used in small quantities to accentuate citrus notes. It is an important intermediate in the manufacture of geranyl esters, citronellol, and citral.

Nerol [*106-25-2*], 3,7-dimethyl-*cis*-2,6-octadien-1-ol, $C_{10}H_{18}O$, M_r 154.25, *bp* (99.3 kPa) 224 – 225 °C, d_4^{20} 0.8796, n_D^{20} 1.4744, occurs in small quantities in many essential oils where it is always accompanied by geraniol; its name originates from its occurrence in neroli oil. Nerol is a colorless liquid with a pleasant roselike odor which, unlike that of geraniol, has a fresh green note.

Nerol undergoes the same reactions as geraniol, but cyclizes more readily in the presence of acids.

Nerol is produced along with geraniol from myrcene in the process described for geraniol (see Geraniol). It can be separated from geraniol by fractional distillation.

Uses. Nerol is used in perfumery not only for the same purposes as geraniol, e.g., in rose compositions, to which it lends a particular freshness, but also in other blossom compositions. In flavor work it is used for bouquetting citrus flavors. Technical-grade nerol, often in a mixture with geraniol, is used as an intermediate in the production of citronellol and citral.

Linalool [*78-70-6*], 3,7-dimethyl-1,6-octadien-3-ol, $C_{10}H_{18}O$, M_r 154.25, *bp* (101.3 kPa) 198 °C, d_4^{20} 0.8700, n_D^{20} 1.4616, occurs as one of its enantiomers in many essential oils, where it is often the main component. (−)-Linalool [*126-90-9*], for example, occurs at a concentration of 80 – 85 % in Shiu oils from *Cinnamomum camphora; Cayenne linaloe* oil contains

ca. 80 %. (+)-Linalool [*126-91-0*] makes up 60 – 70 % of coriander oil.

Properties. (±)-Linalool [*22564-99-4*] is, like the individual enantiomers, a colorless liquid with a flowery-fresh odor, reminiscent of lily of the valley. However, the enantiomers differ slightly in odor [31]. Together with its esters, linalool is one of the most frequently used fragrance substances and is produced in large quantities.

In the presence of acids, linalool isomerizes readily to geraniol, nerol, and α-terpineol. It is oxidized to citral by chromic acid. Oxidation with peracetic acid yields linalool oxides, which occur in small amounts in essential oils and are also used in perfumery. Hydrogenation of linalool gives tetrahydrolinalool, a stable fragrance compound. Its odor is not as strong as, but fresher than, that of linalool. Linalool can be converted into linalyl acetate by reaction with ketene or an excess of boiling acetic anhydride [32].

Production. In the 1950s nearly all linalool used in perfumery was isolated from essential oils, particularly from rosewood oil. Currently, this method is used only in countries where oils with a high linalool content are available and where the importation of linalool is restricted.

Since linalool is an important intermediate in the manufacture of vitamin E, several large-scale processes have been developed for its production. Preferred starting materials and/or intermediates are the pinenes and 2-methyl-2-hepten-6-one. Most perfumery-grade linalool is synthetic.

1) *Isolation from Essential Oils.* Linalool can be isolated by fractional distillation of essential oils, for example, rosewood oil, Shiu oil, and coriander oil, of which Brazilian rosewood oil is probably the most important.
2) *Synthesis from α-Pinene.* α-Pinene from turpentine oil is selectively hydrogenated to *cis*-pinane [33], which is oxidized with oxygen in the presence of a radical initiator to give a mixture of ca. 75 % *cis*- and 25 % *trans*-pinane hydroperoxide. The mixture is reduced to the corresponding pinanols either with sodium bisulfite ($NaHSO_3$) or a catalyst. The pinanols can be separated by fractional distillation and are pyrolized to linalool: (−)-α-pinene yields *cis*-pinanol and (+)-linalool, whereas (−)-linalool is obtained from *trans*-pinanol [34].

3) *Synthesis from β-Pinene.* For a description of this route, see under Geraniol. Addition of hydrogen chloride to myrcene (obtained from β-pinene) results in a mixture of geranyl, neryl, and linalyl chlorides. Reaction of this mixture with acetic acid–sodium acetate in the presence of copper(I) chloride gives linalyl acetate in 75 – 80 % yield [35]. Linalool is obtained after saponification.
4) *Synthesis from 2-Methyl-2-hepten-6-one.* The total synthesis of linalool starts with 2-methyl-2-hepten-6-one; several large-scale processes have been developed for synthesizing this compound:

a) Addition of acetylene to acetone results in the formation of 3-methyl-1-butyn-3-ol, which is hydrogenated to 3-methyl-1-buten-3-ol in the presence of a palladium catalyst. This product is converted into its acetoacetate derivative with diketene [36] or with ethyl acetoacetate [37]. The acetoacetate undergoes rearrangement when heated (Carroll reaction) to give 2-methyl-2-hepten-6-one:

b) In another process, 2-methyl-2-hepten-6-one is obtained by reaction of 3-methyl-1-buten-3-ol with isopropenyl methyl ether followed by a Claisen rearrangement [38]:

c) A third synthesis starts from isoprene, which is converted into 3-methyl-2-butenyl chloride by addition of hydrogen chloride. Reaction of the chloride with acetone in the presence of a catalytic amount of an organic base [39] leads to 2-methyl-2-hepten-6-one:

d) In another process, 2-methyl-2-hepten-6-one is obtained by isomerization of 2-methyl-1-hepten-6-one [40]. The latter can be prepared in two steps from isobutylene and formaldehyde. 3-Methyl-3-buten-1-ol is formed in the first step [41] and is converted into 2-methyl-1-hepten-6-one by reaction with acetone [42].

2-Methyl-2-hepten-6-one is converted into linalool in excellent yield by base-catalyzed ethynylation with acetylene to dehydrolinalool [43]. This is followed by selective hydrogenation of the triple bond to a double bond in the presence of a palladium–carbon catalyst.

Uses. Linalool is used frequently in perfumery for fruity notes and for many flowery fragrance compositions (lily of the valley, lavender, and neroli). Because of its relatively high volatility, it imparts naturalness to top notes. Since linalool is stable in alkali, it can be used in soaps and detergents. Linalyl esters can be prepared from linalool. Most of the manufactured linalool is used in the production of vitamin E.

Myrcenol [*543-39-5*], 2-methyl-6-methylene-7-octen-2-ol, $C_{10}H_{18}O$, M_r 154.25, *bp* (6.7 kPa) 78 °C, d_4^{20} 0.8764, n_D^{20} 1.4731, is an isomer of geraniol and linalool. It has been identified in Chinese lavender oil [44] and some medicinal plants. It is a colorless liquid with a fresh-flowery, slightly limelike odor. Due to its conjugated double bonds, it tends to polymerize; polymerization can be suppressed by adding inhibitors (e.g., antioxidants such as ionol).

Myrcenol can be prepared by treating myrcene with diethylamine to give a mixture of geranyl- and neryldiethylamine. These compounds are hydrated with a dilute acid to the corresponding hydroxydiethylamines. Deamination to myrcenol is effected by using a palladium–phosphine-cation complex as a catalyst [45].

Myrcenol is used in perfumery to obtain a lifting top note in citrus and lavender compositions.

Citronellol [*26489-01-0*], 3,7-dimethyl-6-octen-1-ol, $C_{10}H_{20}O$, M_r 156.27, *bp* (101.3 kPa) 244.4 °C, d_4^{20} 0.8560, n_D^{20} 1.4558, $[\alpha]_D^{20}$ + resp. − 5 to 6 °, occurs as both (+)-citronellol [*1117-61-9*] and (−)-citronellol [*7540-51-4*] in many essential oils.

(−)-Citronellol isolated from natural sources is often named rhodinol. At present, the name rhodinol is also used for the isopropenyl isomer, α-citronellol; therefore, exclusive use of the systematic name is better.

In many natural products citronellol occurs as a mixture of its two enantiomers; the pure (+) or (−) form is seldom found. (+)-Citronellol dominates in oils from *Boronia citriodora* (total citronellol content ca. 80 %) and *Eucalyptus citriodora* (citronellol content 15 – 20 %). (−)-Citronellol is the predominant enantiomer in geranium and rose oils, both of which may contain up to 50 % citronellols.

Citronellol is a colorless liquid with a sweet roselike odor. The odor of (−)-citronellol is more delicate than that of (+)-citronellol.

Citronellol undergoes the typical reactions of primary alcohols (→ Alcohols, Aliphatic, Chap. 2.2.). Compared with geraniol, which contains one more double bond, citronellol is relatively stable. Citronellol is converted into citronellal by dehydrogenation or oxidation; hydrogenation yields 3,7-dimethyloctan-1-ol. Citronellyl esters are easily prepared by esterification with acid anhydrides.

Production. (−)-Citronellol is still obtained mainly from geranium oil by saponification followed by fractional distillation. Although of high odor quality, it does not possess the true (−)-citronellol odor due to impurities. Much larger quantities of (+)- and (±)-citronellol are used and are prepared by partial or total synthesis.

1) *Synthesis of (+)- and (±)-Citronellol from the Citronellal Fraction of Essential Oils.* (+)-Citronellal is obtained by distillation of Java citronella oil and is hydrogenated to (+)-citronellol in the presence of a catalyst (e.g., Raney nickel). Similarly, (±)-citronellol is prepared from the (±)-citronellal fraction of *Eucalyptus citriodora* oil.
2) *Synthesis of (±)- or Slightly Dextrorotatory Citronellol from Geraniol Fractions of Essential Oils.* This citronellol is produced by catalytic hydrogenation of saponified geraniol fractions (also containing (+)-citronellol) obtained from Java citronella oil, followed by fractional distillation. Selective hydrogenation of the double bond in the 2-position of geraniol in geraniol–citronellol mixtures isolated from essential oils can be achieved by using Raney cobalt as a catalyst; overhydrogenation to 3,7-dimethyloctan-1-ol can be largely avoided by this method [46].

3) *Synthesis of (±)-Citronellol from Synthetic Geraniol– Nerol or Citral.* A considerable amount of commercial synthetic (±)-citronellol is produced by partial hydrogenation of synthetic geraniol and/or nerol. Another starting material is citral, which can be hydrogenated, e.g., in the presence of a catalyst system consisting of palladium, ruthenium, and trimethylamine [47].
4) *Preparation of (−)-Citronellol from Optically Active Pinenes.* (+)- *cis*-Pinane is readily synthesized by hydrogenation of (+)-α-pinene or (+)-β-pinene, and is then pyrolyzed to give (+)-3,7-dimethyl-1,6-octadiene. This

compound is converted into (−)-citronellol (97 % purity) by reaction with triisobutylaluminum or diisobutylaluminum hydride, followed by air oxidation and hydrolysis of the resulting aluminum alcoholate [48].

Uses. Citronellol is one of the most widely used fragrance materials, particularly for rose notes and for floral compositions in general. As flavor material, citronellol is added for bouquetting purposes to citrus compositions. It is the starting material for numerous citronellyl esters and for hydroxydihydrocitronellol, an intermediate in the production of hydroxydihydrocitronellal.

Dihydromyrcenol [*18479-58-8*], 2,6-dimethyl-7-octen-2-ol, $C_{10}H_{20}O$, M_r 156.27, *bp* (1.3 kPa) 77 – 79 °C, d_4^{20} 0.841, is a colorless liquid with a fresh citrus-like odor and a lavender note. It is prepared from 2,6-dimethyl-2,7-octadiene, the pyrolysis product of *cis*-pinane [49], by addition of hydrogen chloride and hydrolysis of the resulting 2,6-dimethyl-2-chloro-7-octene [50].

cis-Pinane

Dihydromyrcenol

Dihydromyrcenol is used in soap perfumes for lime and blossom notes.

Tetrahydrogeraniol [*106-21-8*], 3,7-dimethyloctan-1-ol, $C_{10}H_{22}O$, M_r 158.28, *bp* (101.3 kPa) 212 – 213 °C, d_4^{20} 0.8285, n_D^{20} 1.4355, has been identified in citrus oils and is a colorless liquid with a waxy, rose-petal-like odor. It is prepared by hydrogenation of geraniol or citronellol in the presence of a nickel catalyst and is a byproduct in the synthesis of citronellol from geraniol or nerol. Because of its stability, it is often used to perfume household products.

Tetrahydrolinalool [*78-69-3*], 3,7-dimethyloctan-3-ol, $C_{10}H_{22}O$, M_r 158.28, *bp* (1.3 kPa) 78 – 79 °C, d_4^{20} 0.8294, n_D^{20} 1.4335, is a constituent of honey aroma. It is a colorless liquid with a linalool-like odor that is slightly fresher but distinctly weaker than that of linalool. Tetrahydrolinalool is prepared by catalytic hydrogenation of linalool and is used as a substitute for the less stable linalool in perfuming aggressive media.

Farnesol [*4602-84-0*], 3,7,11-trimethyl-2,6,10-dodecatrien-1-ol, $C_{15}H_{26}O$, M_r 222.37, *bp* (1.6 kPa) 156 °C, d_4^{20} 0.8846, n_D^{20} 1.4890, is a component of many blossom oils. It is a colorless liquid with a linden blossom odor, which becomes more intense when evaporated, possibly due to oxidation.

Of the four possible isomers (due to the double bonds in the 2- and 6-positions), the *trans*–*trans*-isomer is the most common in nature and occurs, for example, in ambrette seed oil. 2-*cis*-6-*trans*-Farnesol has been identified in petitgrain oil Bigarade.

trans-trans-Farnesol

Since the odors of the isomers differ very little, natural farnesol in compositions can be replaced by synthetic farnesol, which is a mixture of isomers obtained by isomerization of nerolidol.

Farnesol is particularly suited for use in flower compositions and is valued for its fixative properties. IFRA recommends to use only qualities containing at least 96 % of the farnesol isomers.

Nerolidol [*7212-44-4*], 3,7,11-trimethyl-1,6,10-dodecatrien-3-ol, $C_{15}H_{26}O$, M_r 222.37, *bp* (1.6 kPa) 145 °C, d_4^{20} 0.8778, n_D^{20} 1.4898, is the sesquiterpene analogue of linalool. Because of the double bond at the 6-position, it exists as *cis*- and *trans*-isomers. Each of these isomers can exist as an enantiomeric pair, since the carbon atom in the 3-position is chiral.

Nerolidol is a component of many essential oils. (+)-*trans*-Nerolidol occurs in cabreuva oil; (−)-nerolidol has been isolated from *Dalbergia parviflora* wood oils.

Synthetic nerolidol consists of a mixture of (±)-*cis*- and (±)-*trans*-nerolidol and is a colorless liquid with a long-lasting, mild flowery odor.

Industrial synthesis of nerolidol starts with linalool, which is converted into geranylacetone by using diketene, ethyl acetoacetate, or isopropenyl methyl ether, analogous to the synthesis of 2-methyl-2-hepten-6-one from 3-methyl-1-buten-3-ol (see page 16). Addition of acetylene and partial hydrogenation of the resultant dehydronerolidol produces a mixture of *cis*- and *trans*-nerolidol racemates.

Nerolidol is used as a base note in many delicate flowery odor complexes. It is also an intermediate in the production of vitamins E and K_1.

2.2.3. Aldehydes and Acetals

Among the acyclic terpene aldehydes, citral and citronellal hold key positions as fragrance and flavor chemicals, as well as starting materials for the synthesis of other terpenoids. Hydroxydihydrocitronellal is one of the most important fragrance compounds. Derivatives of these aldehydes, particularly the lower acetals, are also used as fragrance compounds. Acyclic sesquiterpene aldehydes are not very important as such, but they contribute to the characteristic fragrance and aroma of essential oils, for example, in the case of α- and β-sinensal and sweet orange oil (seepage 94).

Citral [*5392-40-5*], 3,7-dimethyl-2,6-octadien-1-al, $C_{10}H_{16}O$, M_r 152.24, occurs as *cis*- and *trans*-isomers (citral a and b, respectively) analogous to the corresponding alcohols, geraniol and nerol: citral a [*141-27-5*] (geranial), *bp* (2.7 kPa) 118 – 119 °C, d_4^{20} 0.8888, n_D^{20} 1.4898; citral b [*106-26-3*] (neral), *bp* (2.7 kPa) 120 °C, d_4^{20} 0.8869, n_D^{20} 1.4869.

Natural citral is nearly always a mixture of the two isomers. It occurs in lemongrass oil (up to 85 %), in *Litsea cubeba* oil (up to 75 %), and in small amounts in many other essential oils. The citrals are colorless to slightly yellowish liquids, with an odor reminiscent of lemon.

Since citral is an α,β-unsaturated aldehyde with an additional double bond, it is highly reactive and may undergo reactions such as cyclization and polymerization. Geraniol, citronellol, and 3,7-dimethyloctan-1-ol can be obtained from citral by stepwise hydrogenation. Citral can be converted into a number of addition compounds; the *cis*- and *trans*-isomers can be separated via the hydrogen sulfite addition compounds. The condensation of citral with active methylene groups is used on an industrial scale in the synthesis of pseudoionones, which are starting materials for ionones and vitamins.

Production. Since citral is used in bulk as a starting material for the synthesis of vitamin A, it is produced industrially on a large scale. Smaller quantities are also isolated from essential oils.

1) *Isolation from Essential Oils.* Citral is isolated by distillation from lemongrass oil (see p. page 98) and from *Litsea cubeba* oil (see p. page 106). It is the main component of these oils.
2) *Synthesis from Geraniol.* Currently, the most important synthetic procedures are vapor-phase dehydrogenation and oxidation of geraniol or geraniol–nerol mixtures. Catalytic dehydrogenation under reduced pressure using copper catalysts is preferred [51].
3) *Synthesis from Dehydrolinalool.* Dehydrolinalool is produced on a large scale from 2-methyl-2-hepten-6-one and acetylene (see page 16) and can be isomerized to citral in high yield by a number of catalysts. Preferred catalysts include organic orthovanadates [52], organic trisilyl oxyvanadates [53], and vanadium catalysts with silanols added to the reaction system [54].

Dehydro-linalool — Citral

4) *Synthesis from Isobutene and Formaldehyde.* 3-Methyl-3-buten-1-ol, obtained from isobutene and formaldehyde [41], isomerizes to form 3-methyl-2-buten-1-ol [55]. However, it is also converted into 3-methyl-2-butenal by dehydrogenation and subsequent isomerization [56,57]. Under azeotropic conditions in the presence of nitric acid, 3-methyl-2-buten-1-ol and 3-methyl-2-butenal form an acetal (shown below) [58], which eliminates one molecule of 3-methyl-2-buten-1-ol at higher temperatures. The intermediate enol ether undergoes Claisen rearrangement followed by Cope rearrangement to give citral in excellent yield [59]:

Uses. Because of its strong lemon odor, citral is very important for aroma compositions such as citrus flavors. In perfumery it can be used only in neutral media due to its tendency to undergo discoloration, oxidation, and polymerization. Limiting IFRA recommendation. It is used as a starting material in the synthesis of ionones and methylionones, particularly β-ionone, which is an intermediate in vitamin A synthesis.

Citral diethyl acetal [*7492-66-2*], 3,7-dimethyl-2,6-octadien-1-al diethyl acetal, $C_{14}H_{26}O_2$, M_r 226.36, *bp* (2 kPa) 140 – 142 °C, d_4^{20} 0.8730, n_D^{20} 1.4503, is a colorless liquid with a flowery, warm-woody citrus odor. It is relatively stable in alkali and can, therefore, be used in soap.

Citronellal [*106-23-0*], 3,7-dimethyl-6-octen-1-al, $C_{10}H_{18}O$, M_r 154.25, *bp* (101.3 kPa) 207 – 208 °C, d_4^{20} 0.851, n_D^{20} 1.4477, $[\alpha]_D^{20}$ + resp. − 15 °, $[\alpha]_D^{20}$ − 13.1 °, occurs in essential oils in its (+) and (−) forms, often together with the racemate. (+)-Citronellal [*2385-77-5*] occurs in citronella oil at a concentration of up

to 45 %; *Backhousia citriodora* oil contains up to 80 % (−)-citronellal [*5949-05-3*]. Racemic citronellal [*26489-02-1*] occurs in a number of *Eucalyptus citriodora* oils at a concentration of up to 85 %.

Pure citronellal is a colorless liquid with a refreshing odor, reminiscent of balm mint. Upon catalytic hydrogenation, citronellal yields dihydrocitronellal, citronellol, or dihydrocitronellol, depending on the reaction conditions. Protection of the aldehyde group, followed by addition of water to the double bond in the presence of mineral acids or ion-exchange resins results in formation of 3,7-dimethyl-7-hydroxyoctan-1-al (hydroxydihydrocitronellal, see page 24). Acid-catalyzed cyclization to isopulegol is an important step in the synthesis of (−)-menthol (seepage 30).

Production. Citronellal is still isolated from essential oils in considerable quantities; it is also produced synthetically.

1) *Isolation from Essential Oils.* (+)-Citronellal is obtained from citronella oils by fractional distillation. (±)-Citronellal is isolated from *Eucalyptus citriodora* oil (see page 100); when necessary, it is purified by using an addition compound, e.g., the bisulfite derivative.
2) *Synthesis from Geraniol or Nerol.* (±)-Citronellal can be obtained by vapor-phase rearrangement of geraniol or nerol (see page 16) in the presence of, e.g., a barium-containing copper–chromium oxide catalyst [60].

Geraniol / nerol Citronellal

3) *Synthesis from Citronellol.* (±)-Citronellal can also be obtained by dehydrogenation of citronellol (see page 19) under reduced pressure with a copper chromite catalyst [61].
4) *Synthesis from Citral.* Selective hydrogenation of citral to citronellal can be accomplished in the presence of a palladium catalyst in an alkaline alcoholic reaction medium [62].

Uses. Citronellal is used to a limited extent for perfuming soaps and detergents. Its main use is as a starting material for the production of isopulegol, citronellol, and hydroxydihydrocitronellal.

7-Hydroxydihydrocitronellal [*107-75-5*], hydroxycitronellal, 3,7-dimethyl-7-hydroxyoctan-1-al, $C_{10}H_{20}O_2$, M_r 172.27, *bp* (130 Pa) 85 – 87 °C, d_4^{20} 0.9220, n_D^{20} 1.4488, has been reported to occur in essential oils [63]. It is a colorless, slightly viscous liquid with a flowery odor reminiscent of linden blossom and lily of the valley. Commercially available hydroxycitronellal is either optically active or racemic, depending on the starting material used. Hydroxycitronellal prepared from (+)-citronellal, for example, has a specific rotation $[\alpha]_D^{20}$ + 9 to + 10 °.

Hydroxycitronellal is relatively unstable toward acid and alkali and is, therefore, sometimes converted into more alkali-resistant acetals, particularly its dimethyl acetal.

Production. The most important synthetic routes to hydroxydihydrocitronellal are listed below.

1) *Synthesis from Citronellal.* One of the oldest routes to hydroxycitronellal is the hydration of the citronellal bisulfite adduct (obtained at low temperature) with sulfuric acid, followed by decomposition with sodium carbonate. A more recent development is hydration of citronellal enamines or imines, followed by hydrolysis [64].
2) *Synthesis from Citronellol.* Citronellol (see page 19) is hydrated to 3,7-dimethyloctan-1,7-diol, for example, by reaction with 60 % sulfuric acid. The diol is dehydrogenated catalytically in the vapor phase at low pressure to highly pure hydroxydihydrocitronellal in excellent yield. The process is carried out in the presence of, for example, a copper–zinc catalyst [65]; at atmospheric pressure noble metal catalysts can also be used [66].
3) *Synthesis from 7-Hydroxygeranyl–Neryl Dialkylamine.* The starting material can be obtained by treatment of myrcene with a dialkylamine in the presence of an alkali dialkylamide, followed by hydration with sulfuric acid. The 7-hydroxygeranyl–neryl dialkylamine isomerizes to the corresponding 7-hy-

droxyaldehyde enamine in the presence of a palladium(II)–phosphine complex as catalyst. Hydrolysis of the enamine gives 7-hydroxydihydrocitronellal [67].

Uses. Because of its fine, flowery odor, hydroxydihydrocitronellal is used in large quantities in many perfume compositions for creating linden blossom and lily of the valley notes. It is also used in other blossom fragrances such as honeysuckle, lily, and cyclamen. Limiting IFRA recommendation.

Methoxydihydrocitronellal [*3613-30-7*], 3,7-dimethyl-7-methoxyoctan-1-al, $C_{11}H_{22}O_2$, M_r 186.29, *bp* (60 Pa) 60 °C, n_D^{20} 1.4375, is a colorless liquid with a fresh, green, blossom odor and is used in perfumery in floral compositions for fresh-green nuances.

Hydroxydihydrocitronellal dimethyl acetal [*141-92-4*], 3,7-dimethyl-7-hydroxyoctan-1-al dimethyl acetal, $C_{12}H_{26}O_3$, M_r 218.34, *bp* (1.6 kPa) 131 °C, d_4^{20} 0.931, n_D^{20} 1.4419, is a colorless liquid with a weak, flowery odor. Since the acetal is stable to alkali, it is used occasionally in soap perfumes.

Citronellyloxyacetaldehyde [*7492-67-3*], $C_{12}H_{22}O_2$, M_r 198.30, *bp* (1.6 kPa) 128–130 °C, is a colorless, slightly viscous liquid with a delicate-flowery odor reminiscent of rose and lily of the valley. The aldehyde is obtained by hydrolysis (with dilute acetic acid) of its acetals, which are prepared from sodium citronellate and chloroacetaldehyde dialkyl acetals [68]. It is used in perfumery to obtain heavy-flowery effects.

2,6,10-Trimethyl-9-undecenal [*141-13-9*], $C_{14}H_{26}O$, M_r 210.36, *bp* (1.2 kPa) 133–135 °C, d_4^{20} 0.8483, n_D^{20} 1.447–1.453, is a colorless to slightly yellow liquid with an intense aldehyde-waxy, slightly flowery odor. It is synthesized from hydrogenated pseudoionone (primarily the tetrahydro compound) and an alkyl chloroacetate by means of a glycidic ester condensation; this is followed by hydrolysis and decarboxylation.

2,6,10-Trimethyl-9-undecenal is a richly fragrant compound that is used in flower compositions to obtain an aldehydic note.
Trade Names. Adoxal (Givaudan Roure), Farenal (Haarmann & Reimer).

2.2.4. Ketones

Unlike the terpene alcohols, aldehydes, and esters, acyclic terpene ketones are not particularly

important as fragrance or flavor substances; thus, they are not discussed here in detail. 2-Methyl-2-hepten-6-one (see page 16) is an important intermediate in the synthesis of terpenoids. Its odor properties are not impressive. It occurs in nature as a decomposition product of terpenes. Tagetone [*6752-80-3*] is a major component of tagetes oil. Solanone [*1937-54-8*] and pseudoionone [*141-10-6*] are acyclic C_{13} ketones with a terpenoid skeleton. Solanone is one of the flavor-determining constituents of tobacco, pseudoionone is an intermediate in the synthesis of ionones (see page 36).

Tagetone

Solanone

Geranylacetone [*689-67-8*], 6,10-dimethyl-5,9-undecadien-2-one, $C_{13}H_{22}O$, M_r 194.32, *bp* (1.3 kPa) 124 °C, d_4^{20} 0.8729, n_D^{20} 1.4674, occurs in *cis* as well as *trans* form and has been identified in fruits and in essential oils. It is a colorless liquid with a fresh-green, slightly penetrating, roselike odor.

Geranylacetone is an intermediate in nerolidol synthesis (see page 21). It is used in perfumery in rose compositions, for example, in soap perfumes.

trans-Geranylacetone

2.2.5. Acids and Esters

Although a small amount of acyclic terpene acids such as geranic acid and citronellic acid occurs in many essential oils, often as esters, they are rarely used in perfume and flavor compositions.

cis-Geranic acid

Citronellic acid

Methyl geranate is an intermediate in α-damascone synthesis and is sometimes needed in the reconstitution of essential oils. However, the lower fatty acid esters (particularly the acetates) of the acyclic terpene alcohols geraniol, linalool, and citronellol are extremely important both as fragrance and as flavor substances. The acetates occur in many essential oils, sometimes in rather high amounts. Formates, propionates, and butyrates occur less frequently. As a result of the development of large-scale production processes for terpenes, the esters of acyclic terpene alcohols are nearly always made synthetically. All acyclic terpene esters that are used as fragrance and flavor materials can be prepared by direct esterification of the appropriate alcohols. However, special precautions are required for the esterification of linalool.

Because the lower fatty acid esters of geraniol, linalool, and citronellol are important contributors to the odor of many essential oils, these esters are widely used in the reconstitution of such oils, as well as in perfume and flavor compositions. The acetates, particularly linalyl acetate, are most widely used. The use of formates is limited by their relative instability. Higher esters are not important in terms of quantity, but are indispensable for creating specific nuances.

In aroma compositions, fatty acid esters of the acyclic terpene alcohols are used for obtaining citrus notes and for rounding off other flavor types.

The most important and most frequently used acyclic terpene esters are described below.

2.2.5.1. Geranyl and Neryl Esters

Geraniol is described on page 15, nerol on page 16.

Geranyl formate [*105-86-2*], $C_{11}H_{18}O_2$, M_r 182.26, *bp* (101.3 kPa) 229 °C (decomp.), d_4^{20} 0.9209, n_D^{20} 1.4659, is a liquid with a fresh, crisp-herbal-fruity rose odor. It is used as a mod-

ifier of, among others, rose, geranium, and neroli compositions.

Geranyl acetate [*105-87-3*], $C_{12}H_{20}O_2$, M_r 196.29, *bp* (1.5 kPa) 98 °C, d_4^{20} 0.9136, n_D^{20} 1.4624, occurs in varying amounts in many essential oils: up to 60 % in oils from *Callitris* and *Eucalyptus* species, and up to 14 % in palmarosa oil. A smaller amount occurs in, for example, geranium, citronella, petitgrain, and lavender oils. Geranyl acetate is a liquid with a fruity, rose note reminiscent of pear and slightly of lavender. It is used frequently in perfumery to create not only flowery-fruity nuances (e.g., rose), but also for citrus and lavender notes. A small amount is added to fruit aromas for shading.

Geranyl propionate [*105-90-8*], $C_{13}H_{22}O_2$, M_r 210.32, *bp* (101.3 kPa) 253 °C, d_4^{20} 0.9207, n_D^{20} 1.459, has a fruity rose odor and is used in perfumery in heavy blossom fragrances with a secondary fruity note.

Geranyl isobutyrate [*2345-26-8*], $C_{14}H_{24}O_2$, M_r 224.34, *bp* (101.3 kPa) 265 °C, d_4^{20} 0.9209, n_D^{20} 1.4576, is a liquid with a fruity rose odor. It is used in floral perfume compositions and in fruit flavors.

Geranyl isovalerate [*109-20-6*], $C_{15}H_{26}O_2$, M_r 238.37, *bp* (101.3 kPa) 279 °C, d_4^{20} 0.8920, n_D^{20} 1.4640, is a liquid with a strongly fruity rose odor. It is used in perfume and flavor compositions.

Neryl acetate [*141-12-8*], $C_{12}H_{20}O_2$, M_r 196.29, *bp* (3.4 kPa) 134 °C, d_4^{20} 0.9110, n_D^{20} 1.4624, is the *cis*-isomer of geranyl acetate. It is present in helichrysum oil and has also been identified in, among others, neroli oil and petitgrain oil Bigarade. It is a colorless, flowery-sweet-smelling liquid and is used in perfumery for blossom compositions (e.g., orange blossom and jasmin).

2.2.5.2. Linalyl and Lavandulyl Esters

Among the linalyl esters (linalool, see page 16), the acetate is by far the most important fragrance and flavor substance. The formate, propionate, and butyrates are used in small amounts.

Linalyl formate [*115-99-1*], $C_{11}H_{18}O_2$, M_r 182.26, *bp* (1.3 kPa) 100 – 103 °C, d_4^{20} 0.9134, n_D^{20} 1.4530, is a liquid with a fruity odor, reminiscent of bergamot. Linalyl formate is moderately stable and is used in lavender fragrances and eaux de cologne.

Linalyl acetate [*115-95-7*], $C_{12}H_{20}O_2$, M_r 196.29, *bp* (101.3 kPa) 220 °C, d_4^{20} 0.8951, n_D^{20} 1.4500, occurs as its (−)-isomer [*16509-46-9*] as the main component of lavender oil (30 – 60 %, depending on the origin of the oil), of lavandin oil (25 – 50 %, depending on the species), and of bergamot oil (30 – 45 %). It has also been found in clary sage oil (up to 75 %) and in a small amount in many other essential oils. (±)-Linalyl acetate [*40135-38-4*] is a colorless liquid with a distinct bergamot-lavender odor.

Production. Linalyl acetate is synthesized by two methods:

1) Esterification of linalool requires special reaction conditions since it tends to undergo dehydration and cyclization because it is an unsaturated tertiary alcohol. These reactions can be avoided as follows: Esterification with ketene in the presence of an acidic esterification catalyst below 30 °C results in formation of linalyl acetate without any byproducts [69]. Esterification can be achieved in good yield, with boiling acetic anhydride, whereby the acetic acid is distilled off as it is formed; a large excess of acetic anhydride must be maintained by continuous addition of anhydride to the still vessel [32]. Highly pure linalyl acetate can be obtained by transesterification of *tert*-butyl acetate with linalool in the presence of sodium methylate and by continuous removal of the *tert*-butanol formed in the process [70].
2) Dehydrolinalool, obtained by ethynylation of 2-methyl-2-hepten-6-one, can be converted into dehydrolinalyl acetate with acetic anhydride in the presence of an acidic esterification catalyst. Partial hydrogenation of the triple bond to linalyl acetate can be carried out with, for example, palladium catalysts deactivated with lead [71].

Uses. Linalyl acetate is used extensively in perfumery. It is an excellent fragrance material for, among others, bergamot, lilac, lavender,

linden, neroli, ylang-ylang, and phantasy notes (particularly chypre). Smaller amounts are used in other citrus products. Since linalyl acetate is fairly stable toward alkali, it can also be employed in soaps and detergents.

Linalyl propionate [*144-39-8*], $C_{13}H_{22}O_2$, M_r 210.31, *bp* (101.3 kPa) 226 °C, d_4^{20} 0.9009, n_D^{20} 1.4505, is a liquid with a fresh bergamot note, reminiscent of lily of the valley. It is used in perfumery in, for example, bergamot, lavender, and lily of the valley compositions.

Linalyl butyrate [*78-36-4*], $C_{14}H_{24}O_2$, M_r 224.34, *bp* (101.3 kPa) 232 °C, d_4^{20} 0.8987, n_D^{20} 1.4523, is a liquid with a fruity bergamot note and a subdued animalic tone. It is used in lavender perfumes and in many blossom compositions.

Linalyl isobutyrate [*78-35-3*], $C_{14}H_{24}O_2$, M_r 224.34, *bp* (20 Pa) 63 – 65 °C, d_4^{20} 0.8991, n_D^{20} 1.4513, has a fresh-fruity lavender odor, which is more refined than that of the butyrate. It is used in lavender compositions and in several flowery notes.

Lavandulyl acetate [*25905-14-0*] (for formula of lavandulol, see Section 2.2.2), $C_{12}H_{20}O_2$, M_r 196.29, *bp* (1.7 kPa) 106 – 107 °C, d_4^{20} 0.9129, n_D^{20} 1.4561, occurs in its (−)-form at a concentration of ca. 1 % in French lavender oil and lavandin oil. It is a liquid with a fresh-herbal rose odor and is used in perfumery for lavender- and lavandin-oil reconstitutions.

One synthetic route to lavandulyl acetate starts with prenyl acetate, which dimerizes in the presence of a Friedel–Crafts catalyst, such as boron trifluoride–diacetic acid [72].

2.2.5.3. Citronellyl Esters

The following citronellyl esters (citronellol, see page 19) are used in relatively large amounts as fragrance and flavor materials:

Citronellyl formate [*105-85-1*], $C_{11}H_{20}O_2$, M_r 184.28, *bp* (2 kPa) 97 – 98 °C, d_4^{20} 0.8972, n_D^{20} 1.4556, is a liquid with a strongly fruity, roselike odor, which is suitable for fresh top notes in rose and lily of the valley fragrances.

Citronellyl acetate [*67650-82-2*], $C_{12}H_{22}O_2$, M_r 198.30, *bp* (101.3 kPa) 240 °C, d_4^{20} 0.8889, n_D^{20} 1.4515, occurs in many essential oils either as one of its optical isomers or as the racemate. The odor of racemic citronellyl acetate differs little from that of the optical isomers. (±)-Citronellyl acetate is a liquid with a fresh-fruity rose odor. It is often used as a fragrance, for example, for rose, lavender, and geranium notes as well as for eaux de cologne with citrus nuances. Since it is relatively stable to alkali, it can be used in soaps and detergents. Citrus flavors acquire specific character through the addition of citronellyl acetate; it is also used to round off other fruit flavors.

Citronellyl propionate [*141-14-0*], $C_{13}H_{24}O_2$, M_r 212.33, *bp* (2 kPa) 120 – 124 °C, d_4^{20} 0.8851, n_D^{20} 1.4452, is a fresh-fruity, roselike smelling liquid. It is used in perfume and flavor compositions in the same way as the acetate.

Citronellyl isobutyrate [*97-89-2*], $C_{14}H_{26}O_2$, M_r 226.36, *bp* (1.6 kPa) 131 – 132 °C, d_4^{20} 0.8760, n_D^{20} 1.4418, is a liquid with a sweet-fruity note and is used in perfumery for fruity-floral nuances.

Citronellyl isovalerate [*68922-10-1*], $C_{15}H_{28}O_2$, M_r 240.39, *bp* (4 kPa) 194 – 196 °C, d_4^{20} 0.8790, n_D^{20} 1.4429, has a heavy, rosy-herbal odor and is used in oriental perfume compositions among others.

Citronellyl tiglate [*24717-85-9*] (with *trans*-$CH_3CH{=}C(CH_3)COOH$ as the acid component), $C_{15}H_{26}O_2$, M_r 238.37, *bp* (900 Pa) 144 – 145 °C, d_4^{20} 0.9043, is a liquid with a flowery rosy, fruity, mushroom-like odor. It is used in geranium oil reconstitutions.

2.2.6. Miscellaneous Compounds

The number of nitrogen- and sulfur-containing derivatives of acyclic terpenoids that are known to be important fragrance and flavor substances is even smaller than in the non-terpenoid aliphatic series discussed in Section 2.1.6. However, a few nitriles are used in rather large amounts in soap perfumes because of their relatively high stability toward alkali.

Geranyl nitrile [*5146-66-7*], geranonitrile, $C_{10}H_{15}N$, M_r 149.24, *bp* (1.3 kPa) 110 °C, d_4^{20} 0.8642, n_D^{20} 1.4759, occurs as a mixture of its *cis*- and *trans*-isomers. It is a liquid with a crisp-fresh, lemon-like, green odor. The nitrile can be prepared from citral by reaction with hydroxylamine and subsequent dehydration with acetic anhydride.
Trade Name. Citralva (IFF).

Citronellyl nitrile [*51566-62-2*], $C_{10}H_{17}N$, M_r 151.25, *bp* (2 kPa) 110 – 111 °C, d_4^{20} 0.845 – 0.846, n_D^{20} 1.4485 – 1.4500, is a colorless liquid with a strong, lemon-like odor. The nitrile can be prepared from citronellal oxime in the same way as geranic acid nitrile.
Trade Name. Agrunitril (DRAGOCO).

2.3. Cyclic Terpenes

2.3.1. Hydrocarbons

Cyclic terpene hydrocarbons occur in essential oils, sometimes in large amounts. They often serve as starting materials for the synthesis of fragrance and flavor compounds. By themselves they generally contribute relatively little to fragrance and aroma. They are used mainly in household perfumery and for reconstitution of essential oils.

Of the various types of monocyclic terpene hydrocarbons, those with the *p*-menthadiene structure are the most important. Examples are as follows:

Limonene

α-Terpinene

γ-Terpinene

Terpinolene

α-Phellandrene

β-Phellandrene

Of the bicyclic terpene hydrocarbons, the pinenes are by far the most important industrially. Camphene and 3-carene are used as starting materials for fragrance compounds.

α-Pinene

β-Pinene

Camphene

3-Carene

Many cyclic sesquiterpenes of various structural types have been isolated from essential oils. As in the case of the cyclic monoterpene hydrocarbons, a number of the cyclic sesquiterpenes are used as starting materials in the synthesis of fragrance and flavor compounds or for the reconstitution of essential oils. Typical examples are as follows:

Caryophyllene

(+)-Valencene

Thujopsene

α-Cedrene

β-Cedrene

Longifolene

components of artificial essential oils. (IFRA recommendation)

Limonene [*138-86-3*], 1,8-*p*-menthadiene, $C_{10}H_{16}$, M_r 136.24, *bp* (101.3 kPa) 178 °C, d_4^{20} 0.8411, n_D^{20} 1.4726, $[\alpha]_D^{20}$ + or − 126.3 °; (+)-limonene [*5989-27-5*] and (−)-limonene [*5989-54-8*] as well as the racemate (dipentene) [*7705-14-8*] occur abundantly in many essential oils. The (+)-isomer is present in citrus peel oils at a concentration of over 90 %; a low concentration of the (−)-isomer is found in oils from the *Mentha* species and conifers.

Limonene is a liquid with lemon-like odor. It is a reactive compound; oxidation often yields more than one product. Dehydrogenation leads to *p*-cymene. Limonene can be converted into cyclic terpene alcohols by hydrohalogenation, followed by hydrolysis. Nitrosyl chloride adds selectively to the endocyclic double bond; this reaction is utilized in the manufacture of (−)-carvone from (+)-limonene (see page 35).

(+)-Limonene is obtained in large amounts as a byproduct in the production of orange juice; (−)-limonene is isolated in relatively small quantities from essential oils. Racemic limonenes, which are commercially available under the name dipentene, are formed as (by)products in many acid-catalyzed isomerizations of α- and β-pinene. Distillation of the so-called dipentene fraction yields limonenes in varying degrees of purity.

The limonenes are used as fragrance materials for perfuming household products and as

γ-Terpinene [*99-85-4*], 1,4-*p*-menthadiene, $C_{10}H_{16}$, M_r 136.24, *bp* (101.3 kPa) 183 °C, d_4^{20} 0.8493, n_D^{20} 1.4747, is a colorless liquid with an herbaceous citrus odor and can be prepared by isomerization of limonene.

(−)-α-Phellandrene [*4221-98-1*], 1,5-*p*-menthadiene, $C_{10}H_{16}$, M_r 136.24, *bp* (99 kPa) 172 °C, d_4^{20} 0.8410, n_D^{20} 1.4708, $[\alpha]_D^{20}$ − 183 °, is a colorless liquid with a citrus odor and a slight peppery note. It is isolated, for example, from *Eucalyptus dives* oil.

Pinenes are widespread, naturally occurring terpene hydrocarbons. The α- and β-forms occur in varying ratios in essential oils.

α-Pinene [*80-56-8*], 2-pinene, $C_{10}H_{16}$, M_r 136.24, *bp* (101.3 kPa) 156 °C, d_4^{20} 0.8553, n_D^{20} 1.4662, $[\alpha]_D^{20}$ + or − 51.9 °, is the most widespread pinene isomer. (+)-α-Pinene [*7785-70-8*] occurs, for example, in oil from *Pinus palustris*Mill. at a concentration up to 65 %; oil from *Pinus pinaster* Soland. and American oil from *Pinus caribaea* contain 70 % and 70 – 80 %, respectively of the (−)-isomer [*7785-26-4*].

α-Pinene

α-Pinene undergoes many reactions, of which the following are used in the fragrance industry: Upon hydrogenation α-pinene is converted to pinane, which has become an important starting material in the industrial processes used

in the fragrance and flavor industry. α-Pinene can be isomerized to β-pinene with high selectivity for β-pinene formation [73]. Hydration with simultaneous ring opening yields terpineol and *cis*-terpin hydrate. Pyrolysis of α-pinene yields a mixture of ocimene and alloocimene.

Pure α-pinene is obtained by distillation of turpentine oils (see page 118). As a fragrance substance it is used to improve the odor of industrial products. However, it is far more important as a starting material in industrial syntheses, for example, terpineols (see page 33), borneol (see page 34), and camphor (see page 36).

β-Pinene [*127-91-3*], 2(10)-pinene, $C_{10}H_{16}$, M_r 136.24, *bp* (101.3 kPa) 164 °C, d_4^{20} 0.8712, n_D^{20} 1.4763, $[\alpha]_D^{20}$ + or − 22.6 °, occurs in many essential oils. Optically active and racemic β-pinenes are present in turpentine oils, although in smaller quantities than α-pinene.

β-Pinene

β-Pinene is similar to α-pinene in its reactions. Pyrolytic cleavage of β-pinene to myrcene, the starting material for acyclic terpenes, is used on an industrial scale. Addition of formaldehyde results in the formation of nopol; nopyl acetate is used as a fragrance material. β-Pinene is produced in large quantities by distillation of turpentine oils. It is used as a fragrance material in household perfumery. However, most β-pinene is used in the production of myrcene.

2.3.2. Alcohols and Ethers

Although cyclic terpene alcohols occur widely in nature, few have the physiological properties that make them important fragrance or flavor compounds. Exceptions are α-terpineol and (−)-menthol, the latter because of its cooling/refreshing effect. Of the bicyclic monoterpene alcohols, borneol deserves mention.

Many cyclic sesquiterpene alcohols are key odor components in essential oils, for example, cedrol in cedarwood oil, the vetiverols in vetiver oil, and the santalols in sandalwood oil. Since these alcohols have not yet been synthesized on an industrial scale, they are described under the oil in which they occur (Chap. 3). Some of their derivatives, however, are discussed in this section.

Menthol, *p*-menthan-3-ol, $C_{10}H_{20}O$, M_r 156.27, has three asymmetric carbon atoms in its cyclohexane ring and, therefore, occurs as four pairs of optical isomers. The configuration of four of these isomers is given below; the other four are their mirror images.

(−)-Menthol is the isomer that occurs most widely in nature. It is the main component of peppermint and cornmint oils obtained from the *Mentha piperita* and *Mentha arvensis* species. Esterified menthol also occurs in these oils (e.g., as the acetate and isovalerate). Other menthol stereoisomers may be present in these oils as well.

Physical Properties. The eight optically active menthols differ in their organoleptic properties [74]. (−)-Menthol has a characteristic peppermint odor and also exerts a cooling effect. The other isomers do not possess this cooling effect and are, therefore, not considered to be "refreshing". (±)-Menthol occupies an intermediate position; the cooling effect of the (−)-menthol present is distinctly perceptible.

The enantiomeric menthols have identical physical properties (apart from their specific rotation), but the racemates differ from the optically active forms in, for example, their melting points. Although the differences between the boiling points of the stereoisomers are small, the four racemates can be separated from each other

by fractional distillation. Boiling points (in °C at 101.3 kPa) are as follows:

Neomenthol	211.7
Neoisomenthol	214.6
Menthol	216.5
Isomenthol	218.6

Other physical constants of commercially available levorotatory and racemic menthols are: (−)-menthol [*2216-51-5*], *mp* 43 °C, n_D^{20} 1.4600, $[\alpha]_D^{20}$ −50 °; (±)-menthol [*15356-70-4*], *mp* 38 °C, n_D^{20} 1.4615.

Chemical Properties. Hydrogenation of menthols yields *p*-menthane; oxidation with chromic acid or catalytic dehydrogenation yields menthones. Dehydration under mild conditions yields 3-*p*-menthene as the main product. Reaction with carboxylic acids or their derivatives yields menthyl esters, which are used mainly as aroma substances and in pharmaceutical preparations and formulations. The esterification of menthols with benzoic acid is used on an industrial scale in the resolution of racemic menthol.

Production. Many industrial processes exist for the production of menthols. For (−)-menthol, isolation from peppermint oil (see Mint Oils, page 107) competes with partial and total syntheses. When an optically active compound is used as a starting material, optical activity must be retained throughout the synthesis, which generally consists of several steps. Total syntheses or syntheses starting from optically inactive materials require either resolution of racemic mixtures or asymmetric synthesis of an intermediate. Recently used processes are the following:

1) (−)-*Menthol from Cornmint Oil. Mentha arvensis* oils, which may contain 70–80 % free (−)-menthol, are cooled and the crystals separated by centrifugation. Since the crystalline product contains traces of cornmint oil, this menthol has a slightly herbaceous-minty note. Pure (−)-menthol is obtained by recrystallization from solvents with low boiling points.
2) (−)-*Menthol from Dementholized Cornmint Oil.* Dementholized cornmint oil, from which (−)-menthol has been removed by crystallization and which still contains 40–50 % free menthol, can be reused for producing (−)-menthol. The fairly large quantity of (−)-menthone in the oil (30–50 %) is hydrogenated to form a mixture of mainly (−)-menthol and (+)- neomenthol; the (−)-menthyl esters present (chiefly (−)-menthyl acetate) are saponified. Additional (−)-menthol is then separated from other components by crystallization, distillation, or via the boric acid esters.
3) (−)-*Menthol from* (+)-*Citronellal.* This process uses the readily occurring cyclization of citronellal to isopulegol. (+)-Citronellal can be isolated with an optical purity of ca. 80 % from citronella oil (see page 98). Alternatively, it can be synthesized with a purity of 98 % from dialkylgeranylamine (obtained from myrcene and a dialkylamine) by enantioselective isomerization to (+)-citronellaldialkylenamine followed by hydrolytic cleavage to (+)-citronellal. Isomerization is effected in the presence of a chiral rhodium–phosphine complex as a catalyst [75]. (+)-Citronellal is cyclized in the presence of acidic catalysts (e.g., silica gel) to give a mixture of optically active isopulegol isomers containing ca. 20 % of the corresponding racemates:

(−)-Isopulegol can be isolated from this mixture and hydrogenated to (−)-menthol. The remaining isopulegol stereoisomers can be partly reconverted into (+)-citronellal by pyrolytic cleavage and reused in the cyclization procedure [76].

The isopulegol mixture can also be hydrogenated to produce a mixture of menthols; the individual stereoisomers are then sep-

arated by distillation. To obtain optically pure (−)-menthol, a resolution step involving a suitable crystalline derivative (such as the benzoate) is required. The undesired stereoisomeric menthols, mainly (+)-neomenthol and (+)-isomenthol, are epimerized to an equilibrium mixture (e.g., by heating in the presence of sodium menthylate). (−)-Menthol is then again separated from the mixture.

4) (−)-*Menthol from* (−)-*Piperitone or Piperitol.* (−)-Menthol can also be prepared from (−)-piperitone, the main component of *Eucalyptus dives* Typus oils. Hydrogenation in the presence of Raney nickel yields a mixture of menthols, from which (−)-menthol can be separated by crystallization and saponification of its chloroacetate.
Analogously, (+)-*trans*-piperitol (obtained from α- or β-phellandrene via piperityl chloride [77]) can be hydrogenated to give a mixture of 97 % (+)-isomenthol and 3 % (+)-menthol. Pure (+)-isomenthol is obtained by crystallization and undergoes rearrangement to give an equilibrium mixture of (+)-neomenthol and (−)-menthol; the latter is separated by distillation.
5) (−)-*Menthol from* (+)-*3-Carene.* An Indian manufacturing process for (−)-menthol starts from 3-carene, the major component of Indian turpentine oil (55 – 65 %). (+)-3-Carene isomerizes to (+)-2-carene, which can be pyrolyzed to (+)-*trans*-2,8-*p*-menthadiene. Isomerization of the latter yields (+)-isoterpinolene, which is hydrogenated to give > 50 % (+)-3-*p*-menthene. Epoxidation and subsequent rearrangement lead to a menthone–isomenthone mixture, which gives a mixture of menthols when it is catalytically hydrogenated. Fractional distillation and crystallization yield commercially acceptable (−)-menthol [78].
6) (−)-*Menthol from* (±)-Menthol. (±)-Menthol can be prepared via several routes and subsequently resolved into the optical isomers:
   a) Racemic menthol can be synthesized by hydrogenation of thymol. This yields a mixture containing the four stereoisomeric menthols in various proportions. (±)-Menthol is separated from the other isomers by distillation.

Thymol Menthol

The remaining isomeric menthols, neomenthol, isomenthol, and a trace of neoisomenthol, can be epimerized, under the conditions used for the thymol hydrogenation, to give ca. 6 : 3 : 1 equilibrium mixture of (±)-menthol, (±)-neomenthol, and (±)-isomenthol, respectively. (±)-Menthol can, again, be distilled from the equilibrium mixture.
   b) (±)-Menthol can be resolved into its optical antipodes by several routes. A large-scale industrial process utilizes selective crystallization of either (+)- or (−)-menthyl benzoate by seeding saturated solutions or supercooled melts of (±)-menthyl benzoates with crystals of (+)- or (−)-menthyl benzoate. Pure (+)- or (−)-menthol is obtained following hydrolysis of the esters [79]. The undesired (+)-menthol can be reconverted into the racemate. Biochemical resolution methods have also been developed [80].

Uses. Because of its cooling and refreshing effect, (−)-menthol is used in large quantities in cigarettes, cosmetics, toothpastes, chewing gum, sweets, and medicines. (±)-Menthol can be used in medicines and liniments.

Isopulegol, 8-*p*-menthen-3-ol, $C_{10}H_{18}O$, M_r 154.25, pure (−)-isopulegol [*89-79-2*], *bp* (1 kPa) 74 °C, d_4^{26} 0.9062, n_D^{26} 1.4690, $[\alpha]_D^{26}$ − 23.6 °. Like menthol, isopulegol has three asymmetric carbon atoms and, therefore, four stereoisomers, each occurring as a pair of optically active antipodes.

The isopulegols occur in a large number of essential oils, often in optically active or part-

ly racemic form. Since citronellal readily cyclizes to isopulegol, the latter occurs frequently in citronellal-containing essential oils, in which it is formed during the recovery of the oil.

Isopulegol produced industrially from (+)-citronellal is a mixture of isomers containing a high percentage of (−)-isopulegol. The isopulegols are colorless liquids with a minty-herbaceous odor. They are converted into the corresponding menthols by means of hydrogenation. Cyclization of citronellal, in the presence of acidic catalysts, yields a mixture of isomeric isopulegols; (+)-citronellal obtained synthetically or from citronella oil is most frequently used as the starting material.

Isopulegol is used in perfumery in various blossom compositions, as well as for geranium notes. It is an important intermediate in (−)-menthol production.

Terpineols are unsaturated monocyclic terpene alcohols and are formed by acid-catalyzed hydration of pinenes; α-, β-, γ-, and δ-isomers exist:

α- and β-Terpineol occur in optically active forms and as racemates. α-Terpineol is an important commercial product. It occurs in a large number of essential oils, primarily as (−)-α-terpineol (for example, in conifer and lavandin oils). Small quantities of (+)- and (±)-α-terpineol are found in many other essential oils; β-, γ-, and δ-terpineol do not occur widely in nature.

α-Terpineol [*98-55-5*], 1-*p*-menthen-8-ol, $C_{10}H_{18}O$, M_r 154.25, *mp* (pure enantiomers) 40–41 °C, *mp* (racemate) 35 °C, *bp* (101.3 kPa) 218–219 °C, d_4^{20} 0.9357, n_D^{20} 1.479, $[\alpha]_D$ +106.4° (solution in ether, 4 %) is a colorless, crystalline solid, smelling of lilac. The most important commercial grade of terpineol consists of a liquid mixture of isomers, that contains mainly α-terpineol and a considerable amount of γ-terpineol. This mixture has a stronger lilac odor than does pure crystalline α-terpineol.

Hydrogenation of α-terpineol yields *p*-menthan-8-ol. Terpineol is readily dehydrated by acids, yielding a mixture of unsaturated cyclic terpene hydrocarbons. Under mildly acidic conditions, terpin hydrate is formed. The most important reaction for the fragrance industry is esterification, particularly acetylation to terpinyl acetate.

Production. Although α-terpineol occurs in many essential oils, only small quantities are isolated, e.g., by fractional distillation of pine oils.

A common industrial method of α-terpineol synthesis consists of the hydration of α-pinene or turpentine oil with aqueous mineral acids to give crystalline *cis*-terpin hydrate (*mp* 117 °C), followed by partial dehydration to α-terpineol. Suitable catalysts are weak acids or acid-activated silica gel [81].

Selective conversion of pinene, 3-carene, and limonene or dipentene to terpineol, without terpin hydrate formation, is also used. Addition of organic acids (weak acids require catalytic amounts of mineral acids) produces terpinyl esters, which are subsequently hydrolyzed to terpineol, sometimes in situ.

Uses. Terpineol with its typical lilac odor is one of the most frequently used fragrance compounds. It is stable and inexpensive, and is used in soaps and cosmetics.

1-Terpinen-4-ol [*562-74-3*], 1-*p*-menthen-4-ol, $C_{10}H_{18}O$, M_r 154.25, *bp* (101.3 kPa) 212 °C, *bp* (500 Pa) 73.5 °C, d^{20} 0.9315, n_D^{20} 1.4799, occurs as (+)-, (−)-, and racemic 1-terpinen-4-ol in many essential oils (e.g., from *Pinus* and *Eucalyptus* species) and in lavender oil. It is a colorless liquid with a spicy, nutmeg-like, woody-earthy, and also lilac-like odor.

1-Terpinen-4-ol is a byproduct in the synthesis of terpineol from terpin hydrate, and occurs in commercial terpineol. Pure 1-terpinen-4-ol can be prepared from terpinolene by photosensitized oxidation, reduction of the resulting 1-methyl-4-isopropenyl-1-cyclohexene-4-hydroperoxide, and selective hydrogenation of the corresponding alcohol [82].

It is used, for example, in artificial geranium and pepper oils and in perfumery for creating herbaceous and lavender notes.

Borneol [*507-70-0*], 2-bornanol, $C_{10}H_{18}O$, M_r 154.25, *mp* (pure enantiomers) 208 °C, *mp* (racemate) 210.5 °C, d_4^{20} 1.011, $[\alpha]_D^{20}$ + or − 37.7 °, is a bicyclic terpene alcohol. Borneol is an *endo* isomer; the corresponding *exo* isomer is isoborneol [*124-76-5*]:

Borneol occurs abundantly in nature as a single enantiomer or, less frequently, as the racemate. (−)-Borneol [*464-45-9*] occurs particularly in oils from Pinaceae species and in citronella oil. (+)-Borneol [*464-43-7*] is found, for example, in camphor oil (Hon-Sho oil), in rosemary, lavender, and olibanum oils.

Borneol is a colorless, crystalline solid. (+)-Borneol has a camphoraceous odor, with a slightly sharp, earthy-peppery note, which is less evident in (−)-borneol. Commercial borneol is often levorotatory ($[\alpha]_D^{20}$ − 18 to − 28 ° in ethanol), and contains (−)-borneol and up to 40 % isoborneol.

Borneol is oxidized to camphor with chromic or nitric acid; dehydration with dilute acids yields camphene. Borneol is readily esterified with acids, but on an industrial scale bornyl esters are prepared by other routes. For example, levorotatory borneol is synthesized industrially from levorotatory pinenes by Wagner-Meerwein rearrangement with dilute acid, followed by hydrolysis of the resulting esters [83].

Borneol is used in the reconstitution of the essential oils in which it occurs naturally.

Cedryl methyl ether [*19870-74-7*], 1*H*-3a,7-methanoazulene, octahydro-6-methoxy-3,6,8,8-tetramethyl-(6*β*), and [*67874-81-1*], 1*H*-3a,7-methanoazulene, octahydro-6-methoxy-3,6,8,8-tetramethyl-(6*α*), $C_{16}H_{18}O$, M_r 236.40, d_{25}^{25} 0.974 – 0.979, n_D^{20} 1.494 – 1.498, is a colorless liquid with a fine cedarwood odor and a distinct amber nuance. It is prepared by methylation of cedrol and is used in perfumes, soaps, and cosmetics.
Trade Name. Cedramber (IFF).

2.3.3. Aldehydes and Ketones

Cyclic terpene aldehydes occur in essential oils only in low concentration. These aldehydes are seldom used as single fragrance compounds.

A few of the cyclic terpene ketones are commercially important as fragrance and flavor compounds, for example, menthone and carvone, which have the *p*-menthane skeleton, and the ionones, which have a (trimethylcyclohexenyl)alkenone skeleton. The ionones and their methyl-substituted homologues are some of the most valuable fragrance materials. Some cyclic terpene ketones are the main components of essential oils (e.g., camphor in camphor oil); others, although not main components, may be essential for a fragrance (e.g., β-damascenone, which is an important component of Bulgarian rose oil; see Rose Oils, page 114). The cyclic sesquiterpene ketone, nootkatone, is one of the characteristic components of grapefruit aroma.

Menthone, *p*-menthan-3-one, $C_{10}H_{18}O$, M_r 154.25, exists as two stereoisomers, menthone and isomenthone, each of which occurs as a pair of enantiomers, due to the two asymmetric centers present in the molecule.

(−)-Menthone

(+)-Isomenthone

Both stereoisomers occur in many essential oils, often as a single enantiomer species. A particularly high concentration (sometimes $>50\,\%$) is found in oils from *Mentha* species. The menthones are colorless liquids that possess a typically minty odor; the odor of isomenthone is slightly musty. They have a strong tendency to interconvert and are, therefore, difficult to obtain in high purity. Industrial products are mixtures of varying composition. Physical constants of industrially important menthone isomers are listed in Table 1.

The menthones are converted into the corresponding menthols by hydrogenation; for example, (−)-menthone yields (+)-neomenthol and (−)-menthol. (−)-Menthone can be obtained by distillation of dementholized cornmint oil or by oxidation of (−)-menthol (e.g., with chromic acid). Dehydrogenation of (−)-menthol (e.g., with copper chromite) yields a mixture of (−)-menthone and (+)-isomenthone. (±)-Menthone is prepared analogously from (±)-menthol. However, it can also be synthesized by hydrogenation of thymol in the presence of palladium–carbon catalysts [84].

Menthone and isomenthone are used for synthetic peppermint oils and bases.

Carvone, 1,8-*p*-menthadien-6-one, $C_{10}H_{14}O$, M_r 150.22, *bp* (101.3 kPa) 230 °C, d_4^{20} 0.960, n_D^{20} 1.499, $[\alpha]_D^{18}$ (+)-carvone +64.3 °, $[\alpha]_D^{20}$ (−)-carvone −62.5 °, occurs as (+)-carvone [*2244-16-8*], (−)-carvone [*6485-40-1*], or racemic carvone [*22327-39-5*]. The optical isomers differ considerably in their organoleptic properties. They occur in high percentages in a number of essential oils. (+)-Carvone is the main component of caraway oil (ca. 60 %) and dill oil; (−)-carvone occurs in spearmint oil at a concentration of 70 – 80 %.

Properties. The carvones are colorless to slightly yellow liquids. (+)-Carvone has an herbaceous odor reminiscent of caraway and dill seeds, whereas (−)-carvone has a herbaceous odor reminiscent of spearmint. Depending on the reaction conditions, hydrogenation of carvone yields either carveols or dihydrocarvone, which are also used as flavor compounds. When treated with strong acids, carvone isomerizes to carvacrol.

Production. In the past, (+)- and (−)-carvones were isolated by fractional distillation of caraway oil and spearmint oil, respectively. However, these carvones are now prepared syn-

Table 1. Physical properties of industrially important menthone isomers

Compound	CAS registry number	*bp* (101.3 kPa), °C	d_t^{20}	n_D^{20}	$[\alpha]_D$
(−)-Menthone	[*14073-97-3*]	210	0.896∗	1.450	−28.5 °
(±)-Menthone	[*1074-95-9*]	210	0.896∗	1.450	
(+)-Isomenthone	[*1196-31-2*]	212	0.900∗∗	1.453	+95.0 °
(±)-Isomenthone	[*36977-92-1*]	212	0.900∗∗	1.453	

$*t = 20\,°C$; $**t = 4\,°C$

thetically, the preferred starting material being (+)- and (−)- limonenes, which are converted into the corresponding optically active carvones. Since optical rotation is reversed in the process, (+)-limonene is the starting material for (−)-carvone.

The preferred industrial method of carvone synthesis utilizes the selective addition of nitrosyl chloride to the endocyclic double bond of limonene. If a lower aliphatic alcohol is used as solvent, limonene nitrosochloride is obtained in high yield. It is converted into carvone oxime by elimination of hydrogen chloride in the presence of a weak base. Acid hydrolysis in the presence of a hydroxylamine acceptor, such as acetone, yields carvone [85].

(+)-Limonene (+)-Limonene nitrosochloride

(−)-Carvone oxime (−)-Carvone

Uses. Both (+)- and (−)-carvone are used to flavor a number of foods and beverages. (−)-Carvone is produced in much larger quantities and is also used in oral hygiene products.

Camphor [*21368-68-3*], 1,7,7-trimethylbicyclo[2.2.1]heptan-2-one, $C_{10}H_{16}O$, M_r 152.24, (+)-camphor: *bp* (101.3 kPa) 204 °C, *mp* 178.8 °C, $[\alpha]_D^{20}$ +44.3 °; both optical isomers are found widely in nature, (+)-camphor [*464-49-3*] being the more abundant. It is, for example, the main component of oils obtained from the camphor tree *Cinnamomum camphora.*

(+)-Camphor

Camphor is produced by fractional distillation and crystallization of camphor oil (see page 90) or, synthetically, by dehydrogenation of isoborneol (from isobornyl acetate, see page 41) over a copper catalyst.

Due to its characteristic penetrating, slightly minty odor, camphor is only used in perfuming industrial products. It is far more important as a plasticizer.

Fenchone [*1195-79-5*], 1,3,3-trimethylbicyclo[2.2.1]heptan-2-one, $C_{10}H_{16}O$, M_r 152.24, *bp* (101.3 kPa) 193 °C, d_4^{20} 0.9484, n_D^{20} 1.4628, $[\alpha]_D^{20}$ + or − 66.8 °, occurs as its (−)-isomer in a number of fennel oils. It is a colorless, slightly viscous liquid with a camphoraceous odor.

(+)-Fenchone

(+)-Fenchone [*7787-20-4*] containing a small amount of the (−)-isomer [*4695-62-9*] is prepared by dehydrogenation of (−)-fenchol. (−)-Fenchyl esters are obtained, along with other compounds, by addition of carboxylic acids to α-pinene. Hydrolysis of the esters yields (−)-fenchol.

Fenchone is used to prepare artificial fennel oils and to perfume household products.

Ionones and Homologous Compounds. The C_{13} ketones α- and β-ionone are cyclic terpenoids that occur in many essential oils. However, being metabolites of the corresponding carotenoids [86], they occur in only small amounts. A third isomer, γ-ionone, has not yet been observed in nature.

α-Ionone

β-Ionone

γ-Ionone

Both optical isomers of α-ionone are found in nature. Generally, ionones have a *trans* config-

uration. *trans*-α-Ionone can be converted into the *cis*-isomer by exposure to ultraviolet light. Under the same conditions, *trans*-β-ionone rearranges to the retro compound.

The *irones* are ionone homologues that have an additional methyl group adjacent to the twin methyl groups in the cyclohexane ring. The number of possible irone isomers is larger than that of the ionones due to the additional methyl group on the ring. Some of these irone isomers occur in essential oils from the roots of *Orris* species (see Orris Root Oil, page 111).

Irone, α-, β-, γ-

n-Methylionone, α-, β-, γ-

Isomethylionone, α-, β-, γ-

Other ionone homologues are the *methylionones,* in which the oxoalkenyl group carries an extra methyl substituent. The methylionones also exist as α-, β-, and γ-isomers, each of which can occur in the *cis* or *trans* form; the isomers may also be optically active. Their natural occurrence is debated [87].

All ionones, irones, and methylionones, as well as the corresponding pseudocompounds (their synthetic acyclic precursors) are slightly viscous yellowish liquids. Commercial irones and methylionones are mixtures of isomers that are named according to their main component. Their composition varies with the method used to prepare and cyclize the pseudocompound and fluctuates considerably between different manufacturers.

Physical and Chemical Properties. Physical and odor properties of the best known ionones are listed in Table 2.

β-Ionone is converted into intermediates for vitamin A synthesis (→ Vitamins, Chap. 2.7.2.). The hydrogenation of ionones and methylionones is of some importance. Dihydro or tetrahydro derivatives or ionols can be obtained depending on reaction conditions.

Table 2. Physical properties of ionones

Name	Formula	CAS registry number	M_r	*bp* °C (*p*, kPa)	d_4^{20}	n_D^{20}	Odor
α-Ionone	$C_{13}H_{20}O$	[*127-41-3*]	192.30	121 – 122 (1.3)	0.9319	1.4982	sweet-floral, reminiscent of violet
β-Ionone	$C_{13}H_{20}O$	[*79-77-6*]	192.30	121.5 (0.93)	0.9461	1.5202	reminiscent of cedarwood, violet-like upon dilution
γ-Ionone	$C_{13}H_{20}O$	[*79-76-5*]	192.30	82 (0.16)	0.9317	1.4985	violet-like with woody-resinous tonality (intermediate in the synthesis of γ-dihydroionone, a component of ambergris)
α-Irone	$C_{14}H_{22}O$	[*79-69-6*]	206.33	109 (0.36)	0.9340	1.4998	responsible for the fragrance of natural orris oil
β-Irone	$C_{14}H_{22}O$	[*79-70-9*]	206.33	108 – 109 (0.21)	0.9465	1.5183	reminiscent of β-ionone, but slightly more intense
α-*n*-Methylionone	$C_{14}H_{22}O$	[*127-42-4*]	206.33	97 (0.35)	0.9210 [a]	1.4938 [b]	reminiscent of α-ionone, but milder and more delicate
β-*n*-Methylionone	$C_{14}H_{22}O$	[*127-43-5*]	206.33	102 (0.35)	0.9370	1.5155	β-ionone-like, but with a distinct leather note
α-Isomethylionone	$C_{14}H_{22}O$	[*127-51-5*]	206.33	130 – 131 (1.3)	0.9345	1.5019	reminiscent of orris and violets, possesses the finest odor of all ionones
β-Isomethylionone	$C_{14}H_{22}O$	[*79-89-0*]	206.33	94 (0.4)	0.9376	1.5053	interesting, powdery, orris-like odor with slightly woody aspects
Allylionone [c]	$C_{16}H_{24}O$	[*79-78-7*]	232.35	102 – 104 (0.02)	0.9289	1.5040	floral violet odor with a fruity pineapple note and high tenacity

[a] d_4^{25}
[b] n_D^{25}
[c] Obtained by cyclization of allylpseudoionone (from citral and allylacetone)

With Raney nickel–copper chromite catalysts, methylionones are converted into tetrahydromethylionols, which are also used as fragrance materials [88].

Production. Ionones, irones, and methylionones, as well as allylionone, are all produced by analogous routes. Special procedures must be used to obtain a particular isomer, either pure or as the main component. These are described where appropriate.

In all processes an acyclic precursor, called a pseudoionone, pseudoirone, etc., is prepared by base-catalyzed condensation of citral or 6-methylcitral with acetone, methyl ethyl ketone, or allylacetone, as appropriate.

In the synthesis of vitamin A, the dependence on natural sources as well as steadily increasing production via β-ionone as an intermediate have led to the development of a method for synthesizing citral from dehydrolinalool (see page 21). More recent routes employ dehydrolinalool as the starting material for pseudoionone. Dehydrolinalool is converted into pseudoionone by using either diketene [89] or a suitably substituted acetoacetate (Carroll reaction) [90]:

A milder reaction for synthesizing pseudoionone from dehydrolinalool is transetherification with an alkoxyalkene [91]:

In the methylionone synthesis, condensation of citral with methyl ethyl ketone results in a mixture of *n*-methyl- and isomethylpseudoionone, each of which may occur as one of four possible *cis–trans*-isomers.

The ratio of the major isomers in the mixture depends on the condensation catalyst and the reaction conditions. In the presence of common alkaline catalysts (e.g., sodium hydroxide), straight-chain isomers are formed preferentially. Strongly alkaline catalysts, such as quaternary ammonium bases, favor the formation of isomethylpseudoionone [92]. This compound is a precursor for the highly valued fragrance substance α-isomethylionone and can be obtained as the main component by reacting dehydrolinalool with the enol ether of methyl ethyl ketone and methanol [93]. Acidic and Lewis catalysts are employed in the cyclization of the pseudocompounds to the cyclic ketones. The primary cyclization products are α-ionone or its homologues, which are isomerized to the β-compounds by strong acids. Concentrated sul-

furic acid converts pseudoionone almost exclusively into β-ionone; 85 % phosphoric acid yields α-ionone in ca. 80 % purity. γ-Ionone can be obtained together with a small amount of α- and β-ionone when boron trifluoride etherate is used as the catalyst and dimethylformamide as the solvent [94]; γ-ionone is of little commercial importance. Since α- and β-ionone can be separated on an industrial scale by fractional distillation in high-performance columns, other methods of separation are seldom used.

Uses. The volume of the production of β-ionone, which serves as an intermediate in vitamin A synthesis, shows that it is by far the most important. The ionones and their homologues are components of blossom and phantasy perfume compositions. The ionones and irones are used in aroma compositions as well, although on a much smaller scale. α-Ionone is a highly valued fragrance material. The methylionones are among the most important fragrance substances, α-isomethylionone being the most important. The irones, isomers of the methylionones, are produced in limited quantities, mainly due to their high cost. Likewise, allylionone is manufactured in small amounts.

Damascones, 1-(2,6,6-trimethylcyclohexenyl)-2-buten-1-ones, $C_{13}H_{20}O$, M_r 192.30, are ionone isomers. Damascone exists in α-, β-, γ-, δ-, and ε-forms, depending on the position of the double bond in the cyclohexane ring. Commercially important are α-damascone [*43052-87-5*], β-damascone ([*23726-91-2*] for (E) and δ-damascone [*57378-68-4*] as mixtures of their *cis*- and *trans*-isomers.

The α- and β-damascones have been identified as components of tea aroma. They are liquids with a fruity, roselike odor. One synthetic route to the damascones starts with an appropriate cyclogeranic acid derivative (halide, ester, etc.). This is reacted with an allyl magnesium halide to give 2,6,6-trimethylcyclohexenyl diallyl carbinol, which on pyrolysis yields the desired 1-(2,6,6-trimethylcyclohexenyl)-3-buten-1-one. Damascone is otained by rearrangement of the double bond in the side-chain [95].

The damascones are used in perfume compositions, especially rose perfumes, and in flavor compositions, to which they impart naturalness and body. (IFRA recommendation)

***β*-Damascenone** [*23726-93-4*], 1-(2,6,6-trimethyl-1,3-cyclohexadienyl)-2-buten-1-one, $C_{13}H_{18}O$, M_r 190.28, is a constituent of Bulgarian rose oil, which has a powerful fragrance although it is only present at a concentration of 0.05 %.

It is used in small quantities in flavor and perfume compositions to impart naturalness and brilliance. (IFRA recommendation)

Nootkatone [*4674-50-4*], 5,6-dimethyl-8-isopropenylbicyclo[4.4.0]-1-decen-3-one, $C_{15}H_{22}O$, M_r 218.33, *mp* 35 °C, has been isolated from grapefruit peel and juice and identified in other citrus oils as well. The commercially available product is a colorless to yellowish liquid with a typical grapefruit odor.

Nootkatone can be prepared by oxidation of valencene, a sesquiterpene hydrocarbon isolated from orange oils. (IFRA recommendation)

Nootkatone is used for flavoring beverages.

Cedryl methyl ketone, $C_{17}H_{26}O$, M_r 246.39, is a long-lasting wood fragrance which is prepared by acetylation of cedarwood oil fractions that contain sesquiterpene hydrocarbons, mainly α-cedrene and thujopsene (for structures, see Section 2.3.1). Acetylation is carried out in the presence of an acidic catalyst (e.g., polyphosphoric acid). Commercially available cedryl methyl ketone is a multicomponent mixture. The main component is 1-(2,6,6,8-tetramethyltricyclo[5.3.1.0^{1,5}]undec-8-en-9-yl)ethan-1-one [*32388-55-9*]. One of its odor-determining compounds is 1-(2,2,8-trimethyltricyclo[6.2.2.0^{1,6}]dodec-5-en-5-yl)ethan-1-one [*32388-56-0*]:

Trade Names. Lignofix (Dragoco), Lixetone (Quest), Vertofix (IFF).

2.3.4. Esters

Esters derived from cyclic terpene alcohols, especially the acetates, are common fragrance and flavor components. Menthanyl, menthenyl, bicyclic bornyl acetates, and a few acetates of sesquiterpene alcohols are extensively used in perfume and aroma compositions.

(−)-Menthyl acetate [*2623-23-6*], (−)-*p*-menthan-3-yl acetate, $C_{12}H_{22}O_2$, M_r 198.30, *bp* (3 kPa) 116 °C, d_4^{20} 0.9253, n_D^{20} 1.4467 – 1.4468, $[\alpha]_D^{20}$ − 81.1 °, occurs in peppermint oils. It is a colorless liquid with a fresh-fruity, peppermint odor.

(−)-Menthyl acetate is prepared by acetylation of (−)-menthol (e.g., with acetic anhydride). It is used mainly in peppermint flavors and reconstituted peppermint oils, but also to a small extent in perfumery.

(±)-Menthyl acetate [*29066-34-0*] occurs in essential oils. It is synthesized by esterification of racemic menthol. Its odor is crisper and less fruity than that of (−)-menthyl acetate. It is used for essential oil compositions and occasionally in household perfumery.

***p*-Menthanyl acetate,** $C_{12}H_{22}O_2$, M_r 198.30, *bp* (200 Pa) 67 – 70 °C, d_{25}^{25} 0.931 – 0.937, n_D^{20} 1.446 – 1.451, is commercially available as a *cis–trans* mixture of *p*-menthan-1-yl acetate [*26252-11-9*] (**1**) and *p*-menthan-8-yl acetate [*80-25-1*] (**2**). It is a colorless liquid with a citrus-fresh, pine-needle odor and a secondary, slightly herbaceous note. Menthanyl acetate is produced by hydrogenation of terpinyl acetates (mixtures of isomers) (e.g., in the presence of Raney nickel [96]) or by esterification of a mixture of isomeric *p*-menthanols.

1

2

The ester mixture is highly stable and is, therefore, used in perfumery for detergents and other household products.

α-Terpinyl acetate [*80-26-2*], 1-*p*-menthen-8-yl acetate, $C_{12}H_{20}O_2$, M_r 196.29, *bp* (5.3 kPa) 140 °C, d_4^{20} 0.9659, n_D^{21} 1.4689, $[\alpha]_D^{20}$ of the enantiomers + or − 79 °; the enantiomers and the racemate occur in many essential oils (e.g., Siberian pine needle oil and cypress oil), but generally not as the main component. Pure α-terpinyl acetates are colorless liquids with a fresh bergamot-lavender odor. Commercially available terpinyl acetate consists mainly of α-terpinyl acetate, but also contains a number of other isomeric compounds. It can be prepared by acetylating the terpineol mixture obtained from terpin hydrate, using a customary procedure for tertiary alcohols.

Because of its odor properties, stability, and low price, large quantities of terpinyl acetate are used in perfumery for lavender and bergamot types, as well as in essential oil reconstitutions.

Nopyl acetate [*35836-72-7*], (−)-2-(6,6-dimethylbicyclo[3.1.1]hept-2-en-2-yl)ethyl acetate, $C_{13}H_{20}O_2$, M_r 208.30, *bp* (1.5 kPa) 122 °C, d_4^{20} 0.9811, n_D^{20} 1.4733, $[\alpha]_D$ −30.9° (CAS registry no. of racemate [*128-51-8*], is not found in nature and has a fresh-fruity-woody odor. (−)-Nopyl acetate is prepared by acetylation of (−)-nopol with acetic anhydride. (−)-Nopol is obtained from (−)-β-pinene and paraformaldehyde in a Prins reaction. Nopyl acetate is used in perfumes for soap and household products.

Bornyl acetate, 2-*endo*-bornanyl acetate, $C_{12}H_{20}O_2$, M_r 196.29, *bp* (101.3 kPa) 223–224 °C, d_4^{20} 0.9838, n_D^{20} 1.4630, $[\alpha]_D^{20}$ + or −44.4°, *mp* (+)- and (−)-form 29 °C, occurs in its optically active forms and as a racemate in many essential oils.

(−)-Bornyl acetate

(−)-Bornyl acetate [*5655-61-8*] is a characteristic component of most conifer oils. It has a camphoraceous, pine-needle-like odor. Both (+)-bornyl acetate [*20347-65-3*] and (−)-bornyl acetate form colorless crystals; the racemate [*36386-52-4*] is a colorless liquid. Bornyl acetate is prepared by esterification of borneol with acetic anhydride or via the process described under borneol (see page 34).

Due to its characteristic pine needle odor, bornyl acetate is frequently used in conifer needle compositions, soap, bath products, room sprays, and pharmaceutical products.

Isobornyl acetate [*125-12-2*], 2-*exo*-bornanyl acetate, $C_{12}H_{20}O_2$, M_r 196.29, *bp* (1.6 – 1.7 kPa) 102 – 103 °C, d_4^{20} 0.9841, n_D^{20} 1.4640, has been identified in a number of essential oils. It is a colorless liquid with a pleasant, pine-needle odor. Isobornyl acetate is prepared from camphene and acetic acid in the presence of acidic catalysts (e.g., sulfuric acid) [97], or ion-exchange resins (e.g., sulfonated styrene–divinylbenzene polymers) [98].

(−)-Camphene (+)-Isobornyl acetate

Isobornyl acetate is used in large amounts for perfuming soap, bath products, and air fresheners. However, the major use of isobornyl acetate is as an intermediate in the production of camphor.

Guaiyl acetate, $C_{17}H_{28}O_2$, M_r 264.41, *bp* (300 Pa) 118 – 123 °C, d_{25}^{25} 0.965 – 0.990, n_D^{20} 1.489 – 1.495, is obtained by esterification of guaiac wood oil with acetic anhydride and consists of the acetates of the natural sesquiterpene alcohols guaiol and bulnesol (see Guaiac Wood Oil, page 103). Guaiyl acetate is a yellow to amber-yellow liquid with a weak but lasting, woody odor. It is used in perfumery for tea-rose and wood nuances.

Cedryl acetate [*77-54-3*], $C_{17}H_{28}O_2$, M_r 264.41, *bp* (400 Pa) 146 – 150 °C, d_{25}^{25} 0.966 – 1.012, n_D^{20} 1.495 – 1.506, occurs in cedarwood oils. The pure compound is crystalline (*mp* 80 °C). Commercial cedryl acetate is a colorless to amber-yellow liquid, with a cedarwood-like odor. It is prepared by esterification of the cedrol-rich fraction from cedarwood oil and is used in perfumery for wood and leather notes, and as a fixative.

Vetiveryl acetate [*62563-80-8*], *bp* (300 Pa) 125 – 128 °C, d_{25}^{25} 0.979 – 1.015, n_D^{20} 1.5050 – 1.5180, is not a single compound; its main component is khusimyl acetate [*61474-33-7*]. Vetiveryl acetate is prepared by esterification of the sesquiterpene alcohols isolated from vetiver oils.

Khusimyl acetate

Vetiveryl acetate is a light yellow liquid with a dry, fresh-woody odor. It is a popular fragrance mixture that is frequently used in luxury perfumery; it is also used as a fixative in many fine fragrances. (Limiting IFRA recommendation)

2.3.5. Miscellaneous Compounds

Of the few known terpene compounds that contain heteroatoms such as nitrogen or sulfur, the thiol 8-mercapto-*p*-menthan-3-one described below has qualitatively important applications as a fragrance and flavor substance. The second thiol, 1-*p*-menthene-8-thiol, is described because its odor threshold value is far lower than that of most other fragrance and flavor compounds.

8-Mercapto-*p*-menthan-3-one [*38462-22-5*], $C_{10}H_{18}OS$, M_r 186.31, *bp* (13 Pa) 57 °C, is an essential odoriferous constituent of buchu leaf oil. The commercial product is synthesized from pulegone and is a liquid mixture of *cis*–*trans*-isomers with a typical blackcurrant odor. 8-Mercapto-*p*-menthan-3-one is prepared by reacting pulegone with hydrogen sulfide in the presence of a base (e.g., triethylamine) [99]:

Pulegone 8-Mercapto-*p*-menthan-3-one

This powerful fragrance and flavor substance is used in perfume and aroma compositions.

1-*p*-Menthene-8-thiol [*71159-90-5*], $C_{10}H_{18}S$, M_r 170.31, *bp* (45 Pa) 40 °C, d_4^{20} 0.948, n_D^{20} 1.503, has been identified in grapefruit juice. It is a liquid with an extremely powerful, obnoxious odor; when diluted it has the typical aroma of fresh grapefruit juice. Its odor threshold value is extremely low: 2×10^{-5} µg/kg for the (+)-R and 8×10^{-5} µg/kg for the (−)-S isomer [100].

2.4. Other Cycloaliphatic Compounds

In addition to cyclic terpenoids, several other cycloaliphatic compounds have above-average importance as fragrance materials; some of them are structurally related to the terpenes. Ketones are most widely represented and include cyclopentanone derivatives, such as the jasmin fragrance compounds, and cyclic ketones with 15 – 17-membered carbon rings, such as muscone [*541-91-3*] and civetone [*542-46-1*], which are constituents of the extremely expensive animal products, musk and civet.

Muscone

Civetone

Many syntheses have been devised for these macrocyclic ketones. However, due to the many steps involved and poor yields, they are not used widely on an industrial scale. Cyclopentadecanone, a natural musk fragrance, and the unsaturated 5-cyclohexadecen-1-one, which has not yet been found in nature, are more easily synthesized. Their odor characteristics are similar to those of muscone and civetone and are, therefore, used instead of them.

A few alicyclic aldehydes are valuable perfume materials and are obtained by Diels – Alder

reactions using terpenes and acrolein. Esters derived from hydrogenated aromatic compounds, such as *tert*-butylcyclohexyl and decahydro-β-naphthyl acetates, are also used in large amounts as fragrance materials.

2.4.1. Alcohols

Some alicyclic alcohols are important as synthetic sandalwood fragrances. The annual world production of natural sandalwood oil is about 100 t with a current price of about $ 400 per kilogram. Due to the limitations of the harvest and this highly fluctuating price, chemists have been searching for cheap synthetic substitutes for this important perfumery ingredient. Since the 1970s a new class of sandalwood products has been developed, which all originate from campholenic aldehyde, an easily available product of the rearrangement of α-pinene epoxide, catalyzed by zinc chloride or zinc bromide.

5-(2,2,3-Trimethyl-3-cyclopenten-1-yl)-3-methylpentan-2-ol [*65113-99-7*] (**3**), $C_{14}H_{26}O$, M_r 210.36, d_4^{20} 0.896 – 0.904, n_D^{20} 1.470 – 1.476, is a fragrance ingredient that does not occur in nature. It is prepared by condensation of campholenic aldehyde with methyl ethyl ketone, followed by selective hydrogenation of the resulting unsaturated ketone [101].

Compound **3** can be used either in a pure state or as a mixture with its byproduct **4** in perfume compositions and soap perfumes.
Trade Name. Sandalore (Givaudan Roure).

2-Ethyl-4-(2,2,3-trimethyl-3-cyclopenten-1-yl)-2-buten-1-ol [*8219-61-6*], $C_{14}H_{26}O$, M_r 208.35, *bp* (3 kPa) 114 – 116 °C, d_4^{20} 0.9160 – 0.9168, n_D^{20} 1.4870 – 1.4880, is another sandelwood-like fragrance also derived from campholenic aldehyde. Aldol condensation of this aldehyde with butyric aldehyde gives an α,β-unsaturated carbonyl compound that can be reduced to an unsaturated alcohol.

Trade Names. Bacdanol (IFF), Bangalol (Quest), Sandolene (Haarmann & Reimer), Sandranol (DRAGOCO).

In addition some other materials of this type are on the market:

Trade Name. Brahmanol (DRAGOCO).

Trade Name. Polysantol (Firmenich).

Trade Name. Ebanol (Givaudan Roure).

Trade Names. Madrol (DRAGOCO), Sandelice (Cognis).

3-*trans*-Isocamphylcyclohexanol [*3407-42-9*], $C_{16}H_{28}O$, M_r 236.40, does not occur in nature. A synthetic mixture of terpenylcyclohexanol isomers has a sandalwood odor. A commercially available mixture containing 3-*trans*-isocamphylcyclohexanol is prepared by reacting camphene and guaiacol in the presence of an acidic catalyst (e.g., boron trifluoride), followed by catalytic hydrogenation of the resulting terpenylguaiacols. In the alkylation reaction, camphene rearranges to the isobornyl, isofenchyl, and isocamphyl skeletons. These substituents may be introduced in guaiacol at four positions. In the subsequent hydrogenation with simultaneous elimination of the methoxy group, additional possibilities for isomerism arise because the hydroxyl group may be either axial or equatorial to the terpenyl moiety. Therefore, the actual content of the desired isomer, 3-*trans*-isocamphylcyclohexanol, is low in most products. The other isomers are either weak in odor or odorless.

A process starting from catechol, instead of guaiacol, yields a mixture with a higher content of 3-*trans*-isocamphylcyclohexanol [102]. Moreover, the process starting from guaiacol has been improved by converting the main component formed in the first step, *p*-isocamphylguaiacol (**5**), into a mixed ether (**6**) by reaction with diethyl sulfate. Nucleophilic cleavage of the ether with alcoholates or Grignard reagents results in a high yield of *m*-isocamphylguethol (**7**), which is hydrogenated catalytically, with concomitant loss of the ethoxy group, to give a high yield of 3-*trans*-isocamphylcyclohexanol (**8**) [103].

IC = Isocamphyl

The mixture is used as such in large amounts as a replacement for sandalwood oil in soaps, cosmetics, and perfume compositions.

Trade Names. Sandela (Givaudan Roure), Sandel H+R (Haarmann & Reimer), Sandiff (IFF), Rhodanthial (Rhodia), Santalex (Takasago).

2.4.2. Aldehydes

2,4-Dimethyl-3-cyclohexene carboxaldehyde [*68039-49-6*], $C_9H_{14}O$, M_r 138.21, *bp* (4 kPa) 94–96 °C, n_D^{25} 1.4696, is prepared as a mixture of its *cis*- and *trans*-isomers by a Diels–Alder reaction of 2-methyl-1,3-pentadiene and acrolein. It is a liquid with a strongly green, slightly herbaceous, citrus note. It is used for perfuming cosmetic preparations as well as household products.

Trade Names. CyclalC (Givaudan Roure), Ligustral (Quest), Triplal (IFF), Vertocitral (Haarmann & Reimer).

4-(4-Methyl-3-penten-1-yl)-3-cyclohexene carboxaldehyde [*37677-14-8*], $C_{13}H_{20}O$, M_r 192.30, is prepared, together with its 3-isomer, by a Diels – Alder reaction of myrcene and acrolein. The mixture has a fresh-fruity, slightly citrus-like odor and is used to perfume household products.

Trade Names. Empetal (Quest), Myrac aldehyde (IFF), Vertomugal (Haarmann & Reimer).

4-(4-Hydroxy-4-methylpentyl)-3-cyclohexene carboxaldehyde [*31906-04-4*] (**9**), $C_{13}H_{22}O_2$, M_r 210.32, *bp* (130 Pa) 120 – 122 °C, d_4^{20} 0.9941, n_D^{20} 1.4915, is a fragrance substance that does not occur in nature. It is a colorless, viscous liquid with a sweet odor reminiscent of lily of the valley. The aldehyde can be prepared by a Diels – Alder reaction of myrcenol and acrolein in the presence of a Lewis catalyst (e.g., zinc chloride) [104]:

Myrcenol Acrolein **9**

Reaction of myrcenol with acrolein at elevated temperatures, without a catalyst, yields a 70 : 30 mixture of the 4- and 3-substituted cyclohexene carboxaldehydes [105]. This mixture is a commercial product. Compound **9** has excellent fixative properties and is used especially in soap and cosmetics perfumery.
Trade Names. Lyral (IFF), Kovanol (Takasago).

2.4.3. Ketones

2-Heptylcyclopentanone [*137-03-1*], $C_{12}H_{22}O$, M_r 182.31, *bp* (1.3 kPa) 130 °C, d^{20} 0.890, n_D^{20} 1.4530, is a fragrance material with a fruity, slightly herbaceous, jasmin odor; it has not yet been found in nature. It is a colorless, viscous liquid prepared by condensation of cyclopentanone with heptanal to give 2-heptylidenecyclopentanone, with subsequent hydrogenation of the double bond.

2-Heptylcyclopentanone and its lower mass homologues 2-pentyl- and 2-hexylcyclopentanone are used in, for example, jasmin, honeysuckle, and lavender compositions.
Trade Names. Fleuramone (IFF), Projasmon P (Haarmann & Reimer).

Dihydrojasmone [*1128-08-1*], 3-methyl-2-pentyl-2-cyclopenten-1-one, $C_{11}H_{18}O$, M_r 166.26, *bp* (2.7 kPa) 87 – 88 °C, d^{25} 0.9157, n_D^{25} 1.4771, is a colorless, slightly viscous liquid with a typical jasmin odor, resembling that of the naturally occurring *cis*-jasmone. Dihydrojasmone can be synthesized by various routes. A preferred method is intramolecular aldol condensation of 2,5-undecanedione, which can be prepared from heptanal and 3-buten-2-one in the presence of a thiazolium salt, such as 5-(2-hydroxyethyl)-4-methyl-3-benzylthiazolium chloride [106]:

Dihydrojasmone

Dihydrojasmone is used in perfumery in jasmin bases and, more generally, in blossomy and fruity fragrances.

***cis*-Jasmone** [*488-10-8*], 3-methyl-2-(2-*cis*-penten-1-yl)-2-cyclopenten-1-one, $C_{11}H_{16}O$, M_r 164.25, *bp* (1.6 kPa) 78 – 79 °C, d^{20} 0.9423, n_D^{20} 1.4989, occurs in jasmin absolute and contributes to its typical jasmin odor. It is a pale yellow, viscous liquid with a strong jasmin odor. Various stereospecific syntheses for *cis*-jasmone have been reported. A patented method involves alkylation of 3-methyl-2-cyclopenten-1-one with *cis*-2-pentenyl chloride in an alkaline

medium in the presence of a phase-transfer catalyst (e.g., tricaprylmethylammonium chloride) [107]:

cis-Jasmone

cis-Jasmone is used in perfumery in fine jasmin bases and floral compositions.

1-(5,5-Dimethylcyclohex-1-en-1-yl)pent-4-en-1-one [*56973-85-4*], and 1-(3,3-dimethylcyclohex-1-en-1-yl)pent-4-en-1-one [*56973-84-3*], $C_{13}H_{20}O$, M_r 192.30, d_4^{20} 1.490, n_{20}^{20} 0.930. The isomeric mixture is a colorless to pale yellow liquid with an extremely powerful and diffusive odor reminiscent of galbanum, with a pineapple and hyacinth character.

The cyclic ketone can be formed by dehydratization of dehydrolinalool (**10**), subsequent alkylation of **11** with allyl chloride to form **12**, acid-catalyzed cyclization of (**12**) and hydrolysis of the product **13** to give a mixture of **14** and **15** [108].

Trade Name. Dynascone (Firmenich).

1,2,3,5,6,7-Hexahydro-1,1,2,3,3-pentamethyl-4*H*-inden-4-one [*33704-61-9*], $C_{14}H_{22}O$, M_r 206.32, d_4^{20} 0.962, n_D^{20} 1.500, has not yet been found in nature. It is colorless to pale yellow solid to semi-solid mass with a diffusive, spicy, musk-like odor with strong floral reinforcement and powdery, velvet nuances.

The indenone **18** can be prepared by hydrogenation of pentamethylindan (**16**) and subsequent oxidation of the intermediate **17** with air over copper acetate to yield the corresponding ketone **18** [109, 110].

Trade Name. Cashmeran (IFF).

Cyclopentadecanone [*502-72-7*], $C_{15}H_{28}O$, M_r 224.39, *mp* 65 – 67 °C, *bp* (7 Pa) 85 °C, is a musk fragrance found in the scent gland of the male civet cat.

A number of syntheses have been developed for its manufacture. In a more recent method,

1,12-dodecanedial is reacted with 1,3-bis(dimethylphosphono)propan-2-one in the presence of a base, preferably in two steps via the intermediates 15-(dimethylphosphono)pentadec-12-en-14-on-1-al and 2,14-cyclopentadecadien-1-one. Subsequent hydrogenation yields cyclopentadecanone [111].

Cyclopentadecanone is used in fine fragrances.

Trade Name. Exalton (Firmenich).

3-Methylcyclopentadec-4/5-en-1-one, (*E*/*Z*) [*82356-51-2*], $C_{16}H_{28}O$, M_r 236.40, d_{20}^{20} 0.925 – 0.935, has a powerful musk odor, reminiscent of musk ketone.

The synthesis of muscenone starts with a condensation of cyclododecanone and dimethyl methylsuccinate, followed by cyclization with polyphosphoric acid. Hydrogenation and elimination yields methylbicyclo[10.3.0]-pentadec-1(12)-ene. Ozonolyses results in a diketone, which is converted via hydrogenation and elimination to the unsaturated muscone [112].

3-Methylcyclopentadec-4/5-en-1-one is used as nitromusk replacer, at low dosage (0.05 – 0.5 %) as a fragrance enhancer, at higher dosage it is "used for its musky character in addition to its boosty effect".

Trade Name. Muscenone (Firmenich).

5-Cyclohexadecen-1-one [*37609-25-9*], $C_{16}H_{28}O$, M_r 236.40, *bp* (10 Pa) 121 °C, n_D^{25} 1.4865, is commercially available as a 40 : 60 mixture of its *cis*- and *trans*-isomers. It is a colorless liquid with an intense musk odor.

A three-step synthesis starts from cyclododecanone (**19**). Reaction with chlorine gives 2-chlorocyclododecanone (**20**) which is reacted with 2 mol of vinylmagnesium chloride to give 1,2-divinylcyclododecan-1-ol (**21**). This is finally converted into 5-cyclohexadecen-1-one by an oxy-Cope rearrangement [113]:

5-Cyclohexadecen-1-one can be added to perfume compositions as a substitute for the natural macrocyclic ketone musks.

Trade Name. TM II SP (Soda Aromatic), Ambretone (Takasago).

2,3,8,8-Tetramethyl-1,2,3,4,5,6,7,8-octahydro-2-naphthalenyl methyl ketone [*54464-57-2*] (**22**), $C_{16}H_{26}O$, M_r 234.38, *bp* (370 Pa) 134 – 135 °C, n_D^{20} 1.4975 – 1.500, is a synthetic amber fragrance. It is prepared by a Diels – Alder reaction of myrcene and 3-methyl-3-penten-2-one in the presence of aluminum chloride and cyclization of the substituted cyclohexenyl methyl ketone intermediate with phosphoric acid. Some 3-acetyl isomer is also formed [114].

22

The ketone is used in perfume bases for soaps, eaux de cologne, and detergent compositions.
Trade Name. Iso E Super (IFF).

3-Methyl-2-cyclopenten-2-ol-1-one [*80-71-7*], $C_6H_8O_2$, M_r 112.13, *mp* (monohydrate) 106 °C, occurs in beechwood tar and has a caramel-like odor. It has been identified as a flavor component in food. Crystals of the compound usually contain 1 mol of water. Synthetic routes of production are of limited importance in comparison with isolation from beechwood tar.

The compound is frequently used in flavor compositions for its caramel note, e.g., in beverages and in confectionery. It is rarely used in perfumery, and then mainly as an intensifier.

2.4.4. Esters

2-*tert*-Butylcyclohexyl acetate [*88-41-5*], $C_{12}H_{22}O_2$, M_r 198.30, *mp* (pure *cis*-isomer) 34.5 – 35.4 °C; commercial product: d_{25}^{25} 0.938 – 0.944, n_D^{20} 1.4500 – 1.4560; this compound does not occur in nature and exists in *cis* and *trans* forms. Pure 2-*cis*-*tert*-butylcyclohexyl acetate is a crystalline solid, with a fruity, agrumen-like odor. The commercial product is a colorless liquid and consists of a mixture of *cis* and *trans*-isomers, which contains 60 – 95 % of the *cis* ester. With an increasing percentage of the *trans*-isomer, the odor becomes more woody-camphory.

The acetate is prepared by esterification of 2-*tert*-butylcyclohexanol, which is obtained from 2-*tert*-butylphenol. It is highly stable and is used for perfuming soap as well as bath and household products.

Trade Names. Agrumex (Haarmann & Reimer), Verdox (IFF).

4-*tert*-Butylcyclohexyl acetate [*32210-23-4*], $C_{12}H_{22}O_2$, M_r 198.30, *bp* (1 kPa) 89 – 95 °C, d_{25}^{25} 0.933 – 0.939, n_D^{20} 1.450 – 1.454, does not occur in nature and exists in *cis* and *trans* forms. The *trans*-isomer has a rich, woody odor, while the odor of the *cis*-isomer is more intense and more flowery. Considerable variations in *cis*–*trans* ratios in commercial mixtures have little effect on the physical constants. Therefore, the composition of mixtures should be determined by gas chromatography.

The ester is prepared by catalytic hydrogenation of 4-*tert*-butylphenol followed by acetylation of the resulting 4-*tert*-butylcyclohexanol [115]. If Raney nickel is used as the catalyst, a high percentage of the *trans*-isomer is obtained. A rhodium–carbon catalyst yields a high percentage of the *cis*-isomer. The *trans* alcohol can be isomerized by alkaline catalysts; the lower-boiling *cis* alcohol is then removed continuously from the mixture by distillation [116].

4-*tert*-Butylcyclohexyl acetate is used particularly in soap perfumes.
Trade Names. 4-*tert*-Butylcyclohexylacetate (Degussa), Oryclon extra (Haarmann & Reimer), Vertenex (IFF).

Decahydro-β-naphthyl acetate [*10519-11-6*], $C_{12}H_{20}O_2$, M_r 196.29, *bp* (650 Pa) 120 °C, d^{25} 1.005 – 1.015, n_D^{25} 1.475 – 1.482, is a fragrance substance that does not occur in nature. It consists of a mixture of several stereoisomers and is a colorless liquid with a sweet-fruity-herbaceous odor and a slight jasmin note.

Decahydro-β-naphthyl acetate is prepared by esterification of technical-grade decahydro-β-naphthol (e.g., with acetic anhydride). The acetate is used for perfuming household products.

4,7-Methano-3a,4,5,6,7,7a-hexahydro-5(or 6)-indenyl acetate [*2500-83-6*] (or [*5413-60-5*]), $C_{12}H_{16}O_2$, M_r 192.26, *bp* (1 kPa) 119 – 121 °C, d_4^{25} 1.0714, n_D^{25} 1.4935, is a colorless liquid with a herbal, fresh-woody odor. It consists of a mixture of isomers that is obtained by addition of acetic acid to dicyclopentadiene in the presence of an acid catalyst. It is used for perfuming soaps, detergents, and air fresheners.

Trade Names. Cyclacet (IFF), Herbaflorat (Haarmann & Reimer), Verdylacetate (Givaudan Roure).

Allyl 3-cyclohexylpropionate [*2705-87-5*], $C_{12}H_{20}O_2$, M_r 196.29, *bp* (130 Pa) 91 °C, has not yet been found in nature. It is a colorless liquid with a sweet-fruity odor, reminiscent of pineapples. The ester is prepared by esterification of 3-cyclohexylpropionic acid (obtained by hydrogenation of cinnamic acid) with allyl alcohol. It is used in perfumery to obtain fruity top notes as well as pineapple and chamomile nuances. (Limiting IFRA recommendation)

Methyl dihydrojasmonate [*24851-98-7*], methyl (3-oxo-2-pentylcyclopentyl)acetate, $C_{13}H_{22}O_3$, M_r 226.32, *bp* (1 Pa) 85 – 90 °C, $d_4^{21.6}$ 1.003, $n_D^{20.2}$ 1.4589, is a jasmin fragrance that is closely related to methyl jasmonate, which occurs in jasmin oil. Methyl dihydrojasmonate has been identified in tea. It is a liquid with a typical fruity, jasmin-like blossom odor. Methyl dihydrojasmonate is prepared as *cis*/*trans*-isomeric mixture by Michael addition of malonic esters to 2-pentyl-2-cyclopenten-1-one (**23**), followed by hydrolysis and decarboxylation of the resulting 2-pentyl-3-oxocyclopentyl malonate (**24**), and esterification of the (2-pentyl-3-oxocyclopentyl)acetic acid (**25**) [117]. Dealkoxycarbonylation of **24** can also be accomplished directly with water at elevated temperature [118].

Methyl dihydrojasmonate is used in perfumery for blossom fragrances, particularly in jasmin types.
Trade Names. Hedione (Firmenich).

***cis*-Methyldihydrojasmonate** [*24851-98-7*], methyl (3-oxo-2-pentylcyclopentyl)acetate, $C_{13}H_{22}O_3$, M_r 226.32, *bp* (7 Pa) 180 °C, d_{20}^{20} 1.001 – 1.009, has an extremely powerful hedionic, jasminic odor.

Although *cis*-methyldihydrojasmonate is the minor isomer of hedione (see page 49), it is the much more intensive one. Its odor threshold is about 20 times lower than that of the *trans*-isomer. Several attempts have been made to synthesize the pure *cis*-isomer. One approach is heating of the *trans*-isomer with sodium carbonate followed by fractional distillation [119, 120]:

A *cis* : *trans* ratio of 96 : 4 was obtained by catalytic asymmetric hydrogenation of the acid in the presence of the chiral ruthenium catalyst DuPhos (**26**):

Due to its thermodynamic instability *cis*-methyldihydrojasmonate is only stable in media having a pH value of 5.5 to 6.5.
Trade Names. Hedione HC (Firmenich), Cepionate (Nippon Zeon).

Methyl 2-hexyl-3-oxocyclopentanecarboxylate [*37172-53-5*] (**27**), $C_{13}H_{22}O_3$, M_r 226.32, *bp* (8 Pa) 85 °C, n_D^{20} 1.4562, is a colorless liquid with a long-lasting, floral, jasmin-like odor, that has only little of the fatty aspect characteristic of many jasmin fragrances. The product has not yet been found in nature.

27

Compound **27** can be prepared by condensing an alkyl α-bromocaprylate with a trialkyl propane-1,1,3-tricarboxylate to give a substituted cyclopentanone. Hydrolysis, decarboxylation, and esterification of the resulting monocarboxylic acid with methanol yields the desired ester [121]. Trialkyl propane-1,1,3-tricarboxylates can be prepared by Michael addition of dialkyl malonates to alkyl acrylates.

Compound **27** is used in perfumery in floral compositions.
Trade Name. Jasmopol (Haarmann & Reimer).

2.5. Aromatic Compounds

2.5.1. Hydrocarbons

A few alkyl- and aralkyl-substituted aromatic hydrocarbons find limited use in perfumery. Examples include *p*-cymene [*99-87-6*], which is a component of many essential oils and when pure has a weak, citrus odor, as well as diphenylmethane [*101-81-5*] which has an odor like geranium:

p-Cymene

Diphenylmethane

2.5.2. Alcohols and Ethers

Phenethyl alcohol is qualitatively and quantitatively one of the most important fragrance substances that belongs to the class of araliphatic alcohols. Its lower homologue (benzyl alcohol) and higher homologue (dihydrocinnamic alcohol) also have characteristic odor properties, but are more frequently used in the form of their esters. Cinnamic alcohol, the most important unsaturated araliphatic alcohol, is valuable for both fragrances and flavors.

The araliphatic alcohols mentioned above occur in many natural fragrances and flavors, but are generally not the main components. These alcohols are nearly always prepared synthetically for use in compositions. The branched-chain homologues of phenethyl and dihydrocinnamic alcohols (dimethyl benzyl carbinol and dimethyl phenethyl carbinol, respectively) are used in fairly large amounts as fragrance materials, but have not been found in nature.

Benzyl alcohol [*100-51-6*], C_7H_8O, M_r 108.14, *bp* (101.3 kPa) 205.4 °C, d_4^{20} 1.0419, n_D^{20} 1.5396, occurs in many essential oils and foods. It is a colorless liquid with a weak, slightly sweet odor. For further details on the chemical properties and synthesis of benzyl alcohol, see→ Benzyl Alcohol, Chap. 3.

Because of its relatively weak odor, benzyl alcohol is used in fragrance and flavor compositions mainly as a solvent and for dilution. It is the starting material for a large number of benzyl esters, which are important fragrance and flavor substances.

Phenethyl alcohol [*60-12-8*], 2-phenylethyl alcohol, $C_8H_{10}O$, M_r 122.17, *bp* (101.3 kPa) 219.8 °C, d_4^{20} 1.0202, n_D^{20} 1.5325, is the main component of rose oils obtained from rose blossoms. It occurs in smaller quantities in neroli oil, ylang-ylang oil, carnation oil, and geranium oils. Since the alcohol is rather soluble in water, losses occur when essential oils are produced by steam distillation.

Properties. Phenethyl alcohol is a colorless liquid with a mild rose odor. It can be dehydrogenated catalytically to phenylacetaldehyde and oxidized to phenylacetic acid (e.g., with chromic acid). Its lower molecular mass fatty acid esters as well as some alkyl ethers, are valuable fragrance and flavor substances.

Production. Many synthetic methods are known for preparing phenethyl alcohol; the following are currently of industrial importance:

Friedel–Crafts Reaction of Benzene and Ethylene Oxide.
In the presence of molar quantities of aluminum chloride, ethylene oxide reacts with benzene to give an addition product, which is hydrolyzed to phenethyl alcohol:

Phenethylalcohol

Formation of byproducts, such as 1,2-diphenylethane, is largely avoided by using an excess of benzene and low temperature. Special purification procedures are required to obtain a pure product that is free of chlorine and suitable for use in perfumery.

Hydrogenation of Styrene Oxide.
According to a patent, excellent yields of phenethyl alcohol are obtained when styrene oxide is hydrogenated at low temperature, using Raney nickel as a catalyst and a small amount of sodium hydroxide [122].

Uses. Phenethyl alcohol is used frequently and in large amounts as a fragrance compound. It is a popular component in rose type compositions, but it is also used in other blossom notes. It is stable to alkali and, therefore, ideally suited for use in soap perfumes.

Phenethyl methyl ether [*3558-60-9*], $C_9H_{12}O$, M_r 136.19, *bp* (94.6 kPa) 185–186 °C, d^{27} 0.9417, n_D^{24} 1.4970, is a colorless liquid with a sharp, rosy-green odor. It is used in oriental type perfumes as well as in artificial keora oil.

Phenethyl isoamyl ether [*56011-02-0*], $C_{13}H_{20}O$, M_r 192.30, d_{25}^{25} 0.901–0.904, n_D^{20} 1.481–1.484, is a colorless liquid with a green, sweet-flowery odor of chamomile blossoms and a secondary, soapy note; it is used in perfumes.

Trade Name. Anther (Quest).

1-Phenylethyl alcohol [*98-85-1*], styrallyl alcohol, $C_8H_{10}O$, M_r 122.17, *mp* 20 °C, *bp* (101.3 kPa) 203 °C, d_4^{20} 1.0135, n_D^{20} 1.5275, has been identified as a volatile component of food (e.g., in tea aroma and mushrooms). The alcohol is a colorless liquid with a dry, roselike odor,

slightly reminiscent of hawthorn. It can be prepared by catalytic hydrogenation of acetophenone. 1-Phenylethyl alcohol is used in small quantities in perfumery and in larger amounts for the production of its esters, which are more important as fragrance compounds.

Dihydrocinnamic alcohol [*122-97-4*], 3-phenylpropanol, hydrocinnamic alcohol, $C_9H_{12}O$, M_r 136.19, *bp* (100 kPa) 237.5 °C, d_4^{20} 1.008, n_D^{20} 1.5278, occurs both in free and esterified form in resins and balsams (e.g., benzoe resin and Peru balsam). It has been identified in fruit and cinnamon.

Hydrocinnamic alcohol is a slightly viscous, colorless liquid with a blossomy-balsamic odor, slightly reminiscent of hyacinths. Esterification with aliphatic carboxylic acids is important because it leads to additional fragrance and flavor compounds.

Hydrocinnamic alcohol is prepared by hydrogenation of cinnamaldehyde. A mixture of hydrocinnamic alcohol and the isomeric 2-phenylpropanol can be obtained from styrene by a modified oxo synthesis. The two isomers can be separated by distillation [123].

Hydrocinnamic alcohol is used in blossom compositions for balsamic and oriental notes.

α,α-Dimethylphenethyl alcohol [*100-86-7*], 1-phenyl-2-methyl-2-propanol, α,α-dimethyl benzyl carbinol, DMBC, $C_{10}H_{14}O$, M_r 150.22, *mp* 24 °C, *bp* (101.3 kPa) 214 – 216 °C, d_4^{20} 0.9840, n_D^{20} 1.5170, has not yet been found in nature. The alcohol has a floral-herbaceous odor, reminiscent of lilac, and is prepared by a Grignard reaction of benzylmagnesium chloride and acetone. It is used in perfumery for various flower notes (e.g., lilac, hyacinth, mimosa). The alcohol is stable to alkali and, thus, is suited for soap perfumes. It is used to prepare a number of esters, which are also used as fragrance compounds.

4-Phenyl-2-methyl-2-butanol [*103-05-9*], α,α-dimethylphenethyl carbinol, $C_{11}H_{16}O$, M_r 164.25, *bp* (1.9 kPa) 124 – 125 °C, $d_4^{20.7}$ 0.9626, $n_D^{20.7}$ 1.5077, is a colorless liquid with a dry-flowery, lily-like odor. It has been identified in cocoa aroma and is prepared by a Grignard reaction of benzylacetone and methylmagnesium chloride. It is used in blossom compositions.

1-Phenyl-3-methyl-3-pentanol [*10415-87-9*], phenethyl methyl ethyl carbinol, $C_{12}H_{18}O$, M_r 178.28, *bp* (1.7 kPa) 129 – 130 °C, d_4^{25} 0.9582, n_D^{20} 1.509 – 1.513, has not yet been found in nature. It is a colorless liquid with a delicate peony, slightly fruity odor. Phenethyl methyl ethyl carbinol can be prepared from benzylacetone and ethylmagnesium chloride by a Grignard reaction. It is used to perfume soap, cosmetics, and detergents.

Cinnamic alcohol [*104-54-1*], 3-phenyl-2-propen-1-ol, $C_9H_{10}O$, M_r 134.18; *trans*-isomer [*4407-36-7*]: *mp* 34 °C, *bp* (101.3 kPa) 257.5 °C, d_4^{20} 1.0440, n_D^{20} 1.5819; this alcohol can exist in *cis* and *trans* forms. Although both isomers occur in nature, the *trans*-isomer is far more abundant and is present, for example, in styrax oil. *trans*-Cinnamic alcohol is a colorless, crystalline solid with a hyacinth-like balsamic odor.

trans-Cinnamic alcohol

Cinnamic alcohol can be dehydrogenated to give cinnamaldehyde and oxidized to give cinnamic acid. Hydrogenation yields 3-phenylpropanol and/or 3-cyclohexylpropanol. Reaction with carboxylic acids or carboxylic

acid derivatives results in the formation of cinnamyl esters, some of which are used as fragrance compounds.

Production. Cinnamic alcohol is prepared on an industrial scale by reduction of cinnamaldehyde. Three methods are particularly useful:

1) In the *Meerwein–Ponndorf reduction,* cinnamaldehyde is reduced to cinnamic alcohol (yield, ca. 85 %) with isopropyl or benzyl alcohol in the presence of the corresponding aluminum alcoholate.
2) A 95 % yield of cinnamic alcohol is obtained by selective hydrogenation of the carbonyl group in cinnamaldehyde with, for example, an *osmium–carbon* catalyst [124].
3) High yields of cinnamic alcohol can be obtained by reduction of cinnamaldehyde with *alkali borohydrides.* Formation of dihydrocinnamic alcohol is thus avoided [125].

Uses. Cinnamic alcohol is valuable in perfumery for its odor and fixative properties. It is a component of many flower compositions (lilac, hyacinth, and lily of the valley) and is a starting material for cinnamyl esters, several of which are valuable fragrance compounds. In aromas, the alcohol is used for cinnamon notes and for rounding off fruit aromas. It is used as an intermediate in many syntheses (e.g., for pharmaceuticals such as the antibiotic chloromycetin). (Limiting IFRA recommendation)

2.5.3. Aldehydes and Acetals

Many of the aldehydes discussed in this section are treated in detail elsewhere (→ Aldehydes, Aliphatic and Araliphatic).

Several araliphatic aldehydes are of special commercial importance as fragrance and flavor materials. These include cinnamaldehyde and its homologues in which the side-chain carries an alkyl substituent; α-amyl- and α-hexylcinnamaldehyde are particularly important. Other important members of this group are the substituted phenylpropanals, 4-isopropyl- and 4-*tert*-butyl-α-methyldihydrocinnamaldehyde. Arylacetaldehydes and arylpropionaldehydes are, in comparison, seldom used in compositions. The corresponding acetals are more stable and are used as well, although their odor is slightly different and significantly weaker.

The simplest araliphatic aldehyde, benzaldehyde and its 4-isopropyl homologue, cuminaldehyde, are used to a limited extent as fragrance and flavor compounds. However, both compounds are used in large quantity for the production of cinnamic and dihydrocinnamic aldehydes, respectively.

Benzaldehyde [*100-52-7*], C_7H_6O, M_r 106.12, *bp* (101.3 kPa) 178.1 °C, d_4^{15} 1.0415, n_D^{20} 1.5463, is the main, characteristic component of bitter almond oil. It occurs in many other essential oils and is a colorless liquid with a bitter almond odor. For further details on the chemical properties and synthesis of benzaldehyde, see → Benzaldehyde, Chap. 3.

Benzaldehyde is used in aroma compositions for its bitter almond odor. It is the starting material for a large number of araliphatic fragrance and flavor compounds.

Phenylacetaldehyde [*122-78-1*], C_8H_8O, M_r 120.15, *bp* (101.3 kPa) 195 °C, d_4^{20} 1.0272, n_D^{20} 1.5255, has been identified in many essential oils and as a volatile constituent of foods. It is a colorless liquid with a sweet-green odor, reminiscent of hyacinth. Since it readily undergoes oxidation and polymerizes, it must be stabilized by addition of antioxidants and by dilution with, for example, diethyl phthalate before use in compositions.

Phenylacetaldehyde can be obtained in high yield by vapor-phase isomerization of styrene oxide, for example, with alkali-treated silica–alumina [126]. Another process starts from phenylethane-1,2-diol, which can be converted into phenylacetaldehyde in high yield. The reaction is performed in the vapor phase in the presence of an acidic silica–alumina catalyst [127].

Phenylacetaldehyde is used in perfume compositions, in particular for hyacinth and rose notes. (IFRA recommendation)

Phenylacetaldehyde dimethyl acetal [*101-48-4*], $C_{10}H_{14}O_2$, M_r 166.22, *bp* (100.2 kPa) 219 – 221 °C, d^{18} 1.004, is a colorless liquid with a strong, rose-petal odor. The dimethyl acetal is more stable than phenylacetaldehyde itself. It imparts a herbal green note to many flower compositions.

Trade Names. Lilas Vert (Firmenich), Viridine (Givaudan Roure).

Dihydrocinnamaldehyde [*104-53-0*], 3-phenylpropanal, $C_9H_{10}O$, M_r 134.18, *bp* (2.7 kPa) 112 °C, d_4^{20} 1.019, n_D^{20} 1.5266, occurs in Sri Lanka cinnamon oil, among others. The aldehyde is a colorless liquid with a strong, flowery, slightly balsamic, heavy hyacinth-like odor. It tends to undergo self-condensation.

Dihydrocinnamaldehyde can be obtained with scarcely any byproducts by selective hydrogenation of cinnamaldehyde. It is used in perfumery for hyacinth and lilac compositions.

Hydratropaldehyde [*93-53-8*], 2-phenylpropanal, $C_9H_{10}O$, M_r 134.18, *bp* (1.5 kPa) 92 – 94 °C, d_4^{20} 1.0089, n_D^{20} 1.5176, is a colorless liquid with a green hyacinth odor. Hydratropaldehyde can be hydrogenated to hydratropic alcohol, which is also used to a limited extent as a fragrance compound. Hydratropaldehyde is obtained from styrene by oxo synthesis; small quantities of the isomeric dihydrocinnamaldehyde are formed as a byproduct. Hydratropaldehyde is used in perfumery in blossom compositions.

Hydratropaldehyde dimethyl acetal [*90-87-9*], $C_{11}H_{16}O_2$, M_r 180.25, n_D^{20} 1.4938, is a liquid with a mushroom-like, earthy odor. It is used for green nuances in flower compositions.

4-Methylphenylacetaldehyde [*104-09-6*], $C_9H_{10}O$, M_r 134.18, *bp* (101.3 kPa) 221 – 222 °C, d_4^{20} 1.0052, n_D^{20} 1.5255, which has been identified in corn oil, is a colorless liquid with a strong green odor. It can be prepared by reaction of 4-methylbenzaldehyde with chloroacetates, followed by hydrolysis of the resulting glycidates and decarboxylation. The aldehyde is used in flower compositions for green notes.

Cyclamenaldehyde [*103-95-7*], 2-methyl-3-(4-isopropylphenyl)propanal, $C_{13}H_{18}O$, M_r 190.28, *bp* (300 Pa) 108 – 108.5 °C, d_4^{20} 0.9502, n_D^{20} 1.5068, has been reported in nutmeg [128]. The commercially available racemate is a colorless to yellowish liquid with an intense flowery odor reminiscent of *Cyclamen europaeum* (cyclamen, sowbread).

Production. Two main processes are used for the industrial synthesis of cyclamenaldehyde:

1) Alkaline condensation of 4-isopropylbenzaldehyde and propanal results, via the aldol **28**, in the formation of 2-methyl-3-(4-isopropylphenyl)-2-propenal (**29**). The unsaturated

aldehyde is hydrogenated selectively to the saturated aldehyde in the presence of potassium acetate and a suitable catalyst, such as palladium–alumina [129]: see previous page.

2) Friedel–Crafts reaction of isopropylbenzene and 2-methylpropenal diacetate (methacrolein diacetate) in the presence of titanium tetrachloride/boron trifluoride etherate gives cyclamenaldehyde enolacetate, which is hydrolyzed to the aldehyde [130]:

Cyclamenaldehyde

Uses. Cyclamenaldehyde is an important component for obtaining special blossom notes in perfume compositions, particularly the cyclamen type. Because of its fresh-flowery aspect, it is also used as the top note in many other blossom fragrances.

4-*tert*-Butyl-α-methyldihydrocinnamaldehyde [*80-54-6*], 2-methyl-3-(4-*tert*-butylphenyl)propanal, $C_{14}H_{20}O$, M_r 204.31, *bp* (800 Pa) 126 – 127 °C, d_4^{20} 0.9390, n_D^{20} 1.5050, is a homologue of cyclamenaldehyde, but is not found in nature. The racemic compound is a colorless to slightly yellow liquid with a mild-flowery odor, reminiscent of cyclamen and lily of the valley.

The aldehyde is prepared by the same routes as cyclamenaldehyde (see under Cyclamenaldehyde, page 54).

A patent describes the following preparation from α-methylcinnamaldehyde. α-Methylcinnamaldehyde (from benzaldehyde and propionaldehyde) is hydrogenated to α-methyldihydrocinnamic alcohol. The alcohol is alkylated with *tert*-butyl chloride or isobutene to 4-*tert*-butyl-α-methyldihydrocinnamic alcohol, which is subsequently dehydrogenated to the desired aldehyde [131].

α-Methylcinnamaldehyde

4-*tert*-Butyl-α-methyldihydrocinnamaldehyde

The compound is more stable than cyclamenaldehyde and is a popular component of flower compositions, particularly lily of the valley and linden types, because of its mild, pleasant, blossom fragrance. Large quantities are used in soap and cosmetic perfumes.

Trade Names. Lilestral (IFF), Lilial (Givaudan Roure).

Cinnamaldehyde [*14371-10-9*], 3-phenyl-2-propenal, C_9H_8O, M_r 132.16, *trans*-isomer *bp* (101.3 kPa) 253 °C, d_4^{20} 1.0497, n_D^{20} 1.6195, is the main component of cassia oil (ca. 90 %) and Sri Lanka cinnamon bark oil (ca. 75 %). Smaller quantities are found in many other essential oils. In nature, the *trans*-isomer is predominant.

trans-Cinnamaldehyde is a yellowish liquid with a characteristic spicy odor, strongly reminiscent of cinnamon. Being an α,β-unsaturated aldehyde, it undergoes many reactions, of which hydrogenation to cinnamic alcohol, dihydrocinnamaldehyde, and dihydrocinnamic alcohol are important. Cinnamic acid is formed by autoxidation.

On an industrial scale, cinnamaldehyde is prepared almost exclusively by alkaline condensation of benzaldehyde and acetaldehyde. Self-condensation of acetaldehyde can be avoided by using an excess of benzaldehyde and by slowly adding acetaldehyde [132].

Cinnamaldehyde is used in many compositions for creating spicy and oriental notes (e.g., soap perfumes). It is the main component of artificial cinnamon oil. In addition, it is an important intermediate in the synthesis of cinnamic alcohol and dihydrocinnamic alcohol.

α-Amylcinnamaldehyde [*122-40-7*], 2-pentyl-3-phenyl-2-propenal, $C_{14}H_{18}O$, M_r 202.30, *bp* (0.7 kPa) 140 °C, d_4^{20} 0.9710, n_D^{20} 1.5381. Its natural occurrence as a genuine product is debatable. It is a light yellow liquid with a flowery, slightly fatty odor, which becomes reminiscent of jasmin when diluted. The aldehyde is relatively unstable and must be stabilized by antioxidants.

It is prepared from benzaldehyde and heptanal in the same way as cinnamaldehyde.

α-Amylcinnamaldehyde

α-Amylcinnamaldehyde is a very popular fragrance substance for creating jasmin notes. It is stable to alkali and long-lasting; large quantities are used, particularly in soap perfumes.

α-Hexylcinnamaldehyde [*101-86-0*], 2-hexyl-3-phenyl-2-propenal, $C_{15}H_{20}O$, M_r 216.32, *bp* (2 kPa) 174 – 176 °C, d^{24} 0.9500, n_D^{25} 1.5268, has not yet been identified in nature. It is a yellow liquid with a mild, slightly fatty, flowery, somewhat herbal odor and a distinct jasmin note. Like the α-amyl homologue, α-hexylcinnamaldehyde must be protected against oxidation by the addition of stabilizers. It is prepared in a manner similar to α-amylcinnamaldehyde by alkaline condensation of excess benzaldehyde with octanal (instead of heptanal). α-Hexylcinnamaldehyde is widely used in flower compositions (e.g., jasmin and gardenia) and, because of its stability to alkali, in soap perfumes.

2.5.4. Ketones (→ Ketones)

The aromatic ketones that occur or are used as fragrance and flavor materials are predominantly aryl methyl ketones, which include acetophenones and β-naphthyl methyl ketone. Several acetylpolymethylindanes and -tetralins are commercially important as musk fragrances. Musk ketone, a substituted nitroacetophenone, is discussed in page 62.

Acetophenone [*98-86-2*], methyl phenyl ketone, C_8H_8O, M_r 120.15, *mp* 20.5 °C, *bp* (101.3 kPa) 202.0 °C, d_4^{20} 1.0281, n_D^{20} 1.5372, is a naturally occurring component of a large number of foods and essential oils. It is a colorless liquid with a penetrating sweet odor, reminiscent of orange blossom.

Acetophenone can be hydrogenated catalytically to 1-phenylethanol. It is obtained as a byproduct in the Hock phenol synthesis and is purified from the high-boiling residue by distillation (→ Ketones, Chap. 7.1.). The quantitites obtained from this source satisfy the present demand.

Acetophenone is used for perfuming detergents and industrial products and is an intermediate in the synthesis of other fragrance compounds.

4-Methylacetophenone [*122-00-9*], *p*-tolyl methyl ketone, $C_9H_{10}O$, M_r 134.18, *mp* 28 °C, *bp* (101.3 kPa) 226 °C, d_4^{20} 1.0051, n_D^{20} 1.5335, has been identified in Brazilian rosewood oil and in pepper. It occurs as colorless crystals with a flowery-sweet odor that is milder than that of acetophenone. 4-Methylacetophenone is prepared from toluene and acetic anhydride or acetyl chloride by a Friedel–Crafts reaction. It is used for blossom notes in mimosa and hawthorn type perfumes, especially in soap perfumes.

Benzylacetone [*2550-26-7*], 1-phenyl-3-butanone, $C_{10}H_{12}O$, M_r 148.20, *bp* (101.3 kPa) 233 – 234 °C, d_4^{22} 0.9849, n_D^{22} 1.5110, has been identified as a volatile component of cocoa. Benzylacetone is a sweet-flowery smelling liquid, which can be prepared by selective hydrogenation of benzylidene acetone (from benzaldehyde and acetone). It is used in soap perfumes.

Methyl β-naphthyl ketone [*93-08-3*], $C_{12}H_{10}O$, M_r 170.21, *bp* (1.7 kPa) 171 – 173 °C, *mp* 56 °C, d_4^{20} 1.171, n_D^{20} 1.6752, has been identified in some essential oils. It smells like orange blossom and is a colorless crystalline solid. It is usually prepared by Friedel–Crafts acetylation of naphthalene (with acetylchloride, acetic anhydride, etc.) in the presence of aluminum chloride. In polar solvents (e.g., nitrobenzene), the percentage of the simultaneously formed α-isomer is lower. Methyl β-naphthyl ketone is used in eaux de cologne, soap perfumes, and detergents. It is a good fixative.

Benzophenone [*119-61-9*], diphenyl ketone, $C_{13}H_{10}O$, M_r 182.22, *bp* (6.3 kPa) 200.5 °C, *mp* 48.1 °C, d^{50} 1.976, has been identified as a flavor component of grapes. It is a colorless crystalline solid with a rosy, slightly geranium-like odor. It can be prepared in several ways (→ Ketones, Chap. 7.3.), for example, by Friedel–Crafts reaction of benzene and benzoyl chloride with aluminum chloride, or of benzene and carbon tetrachloride, and subsequent hydrolysis of the resulting α,α-dichlorodiphenylmethane. Benzophenone can also be prepared by oxidation of diphenylmethane. It is used in flower compositions and as a fixative.

6-Acetyl-1,1,2,3,3,5-hexamethylindane [*15323-35-0*], $C_{17}H_{24}O$, M_r 244.38, *mp* 35 °C, is a synthetic musk fragrance. It is prepared by Friedel–Crafts acetylation of 1,1,2,3,3,5-hexamethylindane, which can be obtained as a 70 : 30 mixture with 1,1,3,5-tetramethyl-3-ethylindane by reacting α,*p*-dimethylstyrene with amylenes or 2-methyl-2-butanol in a mixture of acetic acid and concentrated sulfuric acid [133]:

The indane ketone is a musk fragrance that is stable to light and in soap. It is used in perfumes and cosmetics for its fixative properties as well as its fragrance.
Trade Name. Phantolide (Haarmann & Reimer).

4-Acetyl-1,1-dimethyl-6-*tert*-butylindane [*13171-00-1*], $C_{17}H_{24}O$, M_r 244.38, *mp* 76.7 – 77.2 °C, is a musk fragrance that does not occur in nature. It is prepared by reacting *tert*-

butylbenzene with isoprene in the presence of sulfuric acid, followed by acetylation of the resulting 1,1-dimethyl-6-*tert*-butylindane [134]: see previous page.

The indane is light-stable and is mainly used for perfuming soaps and cosmetics.
Trade Names. Celestolide (IFF), Crysolide (Givaudan Roure).

5-Acetyl-1,1,2,6-tetramethyl-3-isopropylindane [*68140-48-7*], $C_{18}H_{26}O$, M_r 258.40, *bp* (130 Pa) 144 – 146 °C, n_D^{20} 1.5301, is also a musk fragrance that does not occur in nature. It is prepared from toluene and isobutyryl chloride by a Friedel–Crafts reaction that yields *p*-tolyl isopropyl ketone; the ketone is reduced to the corresponding alcohol. Chlorination and treatment with 2-methyl-2-butene yield 1-isopropyl-2,3,3,5-tetramethylindane, which by a Friedel–Crafts reaction with acetyl chloride gives the title compound [135]:

5-Acetyl-1,1,2,6-tetramethyl-3-isopropylindane

It is used in perfume compositions for soaps and detergents.
Trade Name. Traseolide (Quest).

6-Acetyl-1,1,2,4,4,7-hexamethyltetralin [*1506-02-1*], $C_{18}H_{26}O$, M_r 258.40, *mp* 55.5 °C, *bp* (250 Pa) 119 °C, is a synthetic musk fragrance. It is prepared from 1,1,2,4,4,7-hexamethyltetralin, which is obtained by one of the following routes:

1) Reaction of α,*p*-dimethylstyrene with tetramethylethene [136] or 2,3-dimethylbutan-2-ol [133] in an acetic acid–sulfuric acid mixture yields the desired hexamethyltetralin, in addition to polymerized starting materials:

1,1,2,4,4,7-Hexamethyltetralin

2) Reaction of *p*-cymene with 2,2-dimethyl-3-butene (neohexene) and a tertiary alkylhalide (as a hydrogen scavenger) in the presence of catalytic amounts of anhydrous aluminum halide in inert solvents produces a high yield of the hexamethyltetralin [137].

1,1,2,4,4,7-Hexamethyltetralin is subsequently acetylated to 6-acetyl-1,1,2,4,4,7-hexamethyltetralin, e.g., with acetyl chloride and aluminum chloride (see next page).

The product is a light-stable, versatile musk fragrance that is used in soap and cosmetics.
Trade Names. Fixolide (Givaudan Roure), Tonalide (Haarmann & Reimer).

6-Acetyl-1,1,2,4,4,7-hexamethyltetralin

2.5.5. Esters of Araliphatic Alcohols and Aliphatic Acids

Esters of araliphatic alcohols and aliphatic acids are interesting as flavors and fragrances because of their characteristic odor properties. Acetates are the most popular esters. Benzyl acetate is particularly important commercially and occupies a prominent position in the fragrance and flavor industry.

Esters of other fatty acids are used to a lesser extent. In addition to benzyl esters and phenethyl esters, isomeric homologues with substituted side-chains are used in fairly large amounts in perfume compositions because of their special blossom odors. Not all have yet been found in nature. The esters are prepared from the corresponding alcohols via the customary routes (→ Esters, Organic).

Benzyl esters of lower molecular mass fatty acids occur widely in nature. The following are important fragrance and flavor materials:

Benzyl acetate [*140-11-4*], R = CH_3, $C_9H_{10}O_2$, M_r 150.18, *bp* (101.3 kPa) 215 °C, d_4^{20} 1.0550, n_D^{20} 1.5232, is the main component of jasmin and gardenia oils. It occurs as a minor component in a large number of other essential oils and extracts. It is a colorless liquid with a strong, fruity, jasmin odor. Benzyl acetate is prepared by esterification of benzyl alcohol with acetic anhydride (e.g., with sodium acetate as a catalyst) or by reaction of benzyl chloride with sodium acetate (→ Benzyl Alcohol, Chap. 8.2.). In terms of volume, benzyl acetate is one of the most important fragrance and flavor chemicals.

Benzyl propionate [*122-63-4*], R = CH_2CH_3, $C_{10}H_{12}O_2$, M_r 164.20, *bp* (101.3 kPa) 219–220 °C, d_4^{20} 1.0335, n_D^{20} 1.4996, is a liquid with a sweet-fruity odor, which is used in perfumery for floral-fruity notes and in fruit flavor compositions.

Benzyl isovalerate [*103-38-8*], R = $CH_2CH(CH_3)_2$, $C_{12}H_{16}O_2$, M_r 192.26, *bp* (101.3 kPa) 245 °C, d_4^{20} 0.9900, n_D^{20} 1.4878, is a liquid with a heavy, flowery odor, which is used in perfumery for oriental and heavy blossom odors.

Phenethyl Esters. The most commonly used *phenethyl esters* are the following:

Phenethyl acetate [*103-45-7*], R = CH_3, $C_{10}H_{12}O_2$, M_r 164.20, *bp* (101.3 kPa) 232.6 °C, d_4^{20} 1.0883, n_D^{20} 1.5171, occurs in a number of essential oils and is a volatile aroma component of many fruits and alcoholic beverages. Phenethyl acetate is a colorless liquid with a fine rose scent and a secondary, sweet, honey note. It is used in perfumery as a modifier of phenethyl alcohol, e.g., in rose and lilac compositions. In addition, it is used in a large number of aromas, in keeping with its natural occurrence.

Phenethyl isobutyrate [*103-48-0*], R = $CH(CH_3)_2$, $C_{12}H_{16}O_2$, M_r 192.26, *bp* (2 kPa) 122–124 °C, d^{15} 0.9950, n_D^{20} 1.4871, occurs in peppermint oils. It has a heavy, fruity, blossom odor and is used accordingly in perfume and flavor compositions.

Phenethyl isovalerate [*140-26-1*], R = $CH_2CH(CH_3)_2$, $C_{13}H_{18}O_2$, M_r 206.28, *bp* (7.2 kPa) 141–145 °C, d^{15} 0.9845, n_D^{20} 1.4855, has been identified as a volatile aroma component of peppermint oils. The fruitiness of its odor is even more pronounced than that of the isobutyrate. It is used in small quantities for the same purposes as phenethyl isobutyrate.

1-Phenylethyl acetate [*93-92-5*], styrallyl acetate, $C_{10}H_{12}O_2$, M_r 164.20, *bp* (1.3 kPa) 92.5 °C, d_4^{20} 1.0277, n_D^{20} 1.4954, is a liquid with a dry, fruity-green, blossom odor, reminiscent

of gardenia. It can occur in the form of optically active enantiomers, but only the racemate is used in perfumery. Styrallyl acetate is a key ingredient in gardenia fragrances and is added to many other blossom compositions, particularly for dry top notes.

α,α-Dimethylphenethyl Esters. The following α,α-dimethylphenethyl esters are commercially important:

α,α-Dimethylphenethyl acetate [*151-05-3*], R = CH_3, $C_{12}H_{16}O_2$, M_r 192.26, *mp* ca. 30 °C, *bp* (400 Pa) 90 °C, d_{25}^{25} 0.998 – 1.000, n_D^{20} 1.4923, is a colorless liquid with a flowery-woody odor. The ester is used in blossom compositions, e.g., lily of the valley, rose, and geranium.

α,α-Dimethylphenethyl butyrate [*10094-34-5*], R = $(CH_2)_2CH_3$, $C_{14}H_{20}O_2$, M_r 220.31, *bp* (400 Pa) 96 °C, d_{25}^{25} 0.971 – 0.974, n_D^{20} 1.4860 – 1.4900, is a colorless liquid with a slightly herbal, strongly fruity odor, reminiscent of prune and apricot. It is used in perfumery as a modifier of the alcohol and for oriental notes.

Cinnamyl acetate [*103-54-8*], $C_{11}H_{12}O_2$, M_r 176.21, *bp* (1.3 kPa) 139 – 140 °C, d^{22} 1.0520, n_D^{20} 1.5420, is the only ester of cinnamic alcohol of any importance. *trans*-Cinnamyl acetate occurs in cassia oil and is a colorless liquid with a sweet-flowery-fruity, slightly balsamic odor. It is a good fixative and is used in blossom compositions (e.g., lilac and jasmin) and for oriental notes. In aroma compositions, it is used for cinnamon-fruity effects.

2.5.6. Aromatic Acids

Aromatic acids (e.g., benzoic acid) and araliphatic acids (e.g., phenylacetic, cinnamic, and dihydrocinnamic acids) occur in numerous essential oils and have also been identified in the aromas of many foods. However, phenylacetic acid is the only acid that is used in significant quantities as a fragrance and flavor substance.

Phenylacetic acid [*103-82-2*], $C_8H_8O_2$, M_r 136.15, *bp* (101.3 kPa) 265.5 °C, *mp* 78 °C, $d_4^{79.8}$ 1.0809, occurs in Japanese peppermint oil, in neroli oil, and in traces in rose oils. It is a volatile aroma constituent of many foods (e.g., honey). It forms colorless crystals that have a honey odor. For further details on chemical properties and synthesis, see → Phenylacetic Acid.

Because of its intense odor, phenylacetic acid is added to perfumes in small quantities for rounding off blossom odors. Addition to fruit aromas imparts a sweet honey note.

2.5.7. Esters Derived from Aromatic and Araliphatic Acids

The acid moiety generally determines the odor of esters derived from aromatic or araliphatic acids. Unless stated otherwise, the esters are prepared from the corresponding acids or acid derivatives and alcohols by the customary methods (→ Esters , Organic).

2.5.7.1. Benzoates

The following benzoates are used in fairly large quantities as perfumery materials.

Methyl benzoate [*93-58-3*], R = CH_3, $C_8H_8O_2$, M_r 136.15, *bp* (101.3 kPa) 199.6 °C, d_4^{20} 1.0888, n_D^{20} 1.5164, has been found in essential oils (e.g., ylang-ylang and tuberose blossom

oil). It is a colorless liquid with a strong, dry-fruity, slightly phenolic odor. For further properties and synthesis, seeBenzoic Acid and Derivatives, Chap. 8.5. .

Methyl benzoate is used in perfume bases, such as ylang-ylang and tuberose types.

Hexyl benzoate [*6789-88-4*], R=$(CH_2)_5CH_3$, $C_{13}H_{18}O_2$, M_r 206.28, *bp* (102.6 kPa) 272 °C, is a liquid with a balsamic-green, melon-like odor. It is used in perfumery.

Benzyl benzoate [*120-51-4*], R = $CH_2C_6H_5$, $C_{14}H_{12}O_2$, M_r 212.25, *bp* (2.0 kPa) 170–171 °C, *mp* 21–22 °C, d_4^{25} 1.1121, n_D^{20} 1.5680, is the main component of Peru balsam. It occurs in fairly large amounts in a number of blossom concretes and absolutes (e.g., tuberose and hyacinth). It forms either a viscous liquid or solid flakes and has a weak, sweet-balsamic odor. For further properties and synthesis, see Benzoic Acid and Derivatives, Chap. 8.5.

Benzyl benzoate is used in perfumery as a fixative and as a modifier in heavy blossom fragrances.

2.5.7.2. Phenyl acetates

Of the phenyl acetates, the following are particularly important fragrance and flavor substances:

Ethyl phenyl acetate [*101-97-3*], R = CH_2CH_3, $C_{10}H_{12}O_2$, M_r 164.20, *bp* (101.3 kPa) 227 °C, d_4^{20} 1.0333, n_D^{20} 1.4980, is a volatile aroma component of fruit and honey. It is a colorless liquid with a strong, sweet odor reminiscent of honey. Small amounts are used in flower perfumes and in fruit flavors.

Geranyl phenyl acetate [*102-22-7*], R =$CH_2CH{=}C(CH_3)CH_2CH_2CH{=}C(CH_3)_2$, $C_{18}H_{24}O_2$, M_r 272.39, has not been found in nature. It is a yellow liquid with a mild rose odor and a secondary honey note. It is used as a fixative in rose compositions and heavy perfumes.

Phenethyl phenyl acetate [*102-20-5*], R = $CH_2CH_2C_6H_5$, $C_{16}H_{16}O_2$, M_r 240.30, *bp* (600 Pa) 177–178 °C, *mp* 26.5 °C, d_{25}^{25} 0.880, n_D^{20} 1.5496–1.5504, has not yet been identified in natural sources. It occurs as a colorless liquid or crystals, which have a heavy, sweet, rose or hyacinth odor and a distinct honey note. The ester is used particularly in flowery fragrance compositions and as a fixative.

2.5.7.3. Cinnamates

Three cinnamates are of some importance in perfumery:

Methyl cinnamate [*103-26-4*], R = CH_3, $C_{10}H_{10}O_2$, M_r 162.19, *bp* (101.3 kPa) 261.9 °C, *mp* 36.5 °C, d_4^{20} 1.0911, n_D^{21} 1.5766, occurs in essential oils, mostly as the *trans*-isomer. It is the main component of oils isolated from *Alpinia* species (content up to 80 %) and *Ocimum canum* varieties (> 50 %). It has also been identified as a volatile aroma component of cinnamon and strawberries.

Methyl cinnamate is a colorless crystalline solid with a fruity, sweet-balsamic odor. In addition to the common esterification methods, it can be prepared by Claisen condensation of benzaldehyde and methyl acetate in the presence of sodium. Methyl cinnamate is used in soap perfumes, as well as in blossom and oriental perfumes, and is sometimes added to aromas.

Benzyl cinnamate [*103-41-3*], R = $CH_2C_6H_5$, $C_{16}H_{14}O_2$, M_r 238.29, *mp* 35–36 °C, occurs in balsams and balsam oils. It forms white, sweet-balsamic-smelling crystals. Benzyl cinnamate is used as a fixative in perfumes and as a component of heavy, oriental perfumes.

Phenethyl cinnamate [*103-53-7*], R = $CH_2CH_2C_6H_5$, $C_{17}H_{16}O_2$, M_r 252.31, *mp* 65–68 °C, occurs in extracts from *Populus balsamifera* buds. It is a crystalline solid with a heavy, rosy-balsamic odor. It is used as a fixative in blossom fragrances.

2.5.8. Miscellaneous Compounds

Of the few aromatic, nitrogen-containing fragrance substances, the nitro musks are by far the most important. They are still considerably important commercially as substitutes for the natural macrocyclic musks that are difficult to synthesize, but nitro musks are being increasingly replaced by lightfast musk fragrances. Methyl anthranilate and its *N*-methyl derivative are also aromatic, nitrogen-containing compounds that are used as fragrances and flavors in fairly large amounts. A number of aromatic nitriles have been introduced; they are stable to alkali and, therefore, are used in soap perfumes.

Musk xylol [*81-15-2*], 2,4,6-trinitro-1,3-dimethyl-5-*tert*-butylbenzene, $C_{12}H_{15}N_3O_6$, M_r 297.27, *mp* 114 °C, does not occur in nature. It forms yellow crystals with a persistent musk odor. Musk xylol is prepared by alkylation of *m*-xylene with isobutene and subsequent nitration with a sulfuric acid–nitric acid mixture.

Musk xylol

Musk xylol is used in large quantities in inexpensive perfumes for soap and household products.

Musk ketone [*81-14-1*], 3,5-dinitro-2,6-dimethyl-4-*tert*-butylacetophenone, $C_{14}H_{18}N_2O_5$, M_r 294.31, *mp* 137 °C, does not occur in nature. It forms yellowish crystals with a sweet, very persistent, slightly animal musk odor. Musk ketone is prepared by Friedel–Crafts acetylation of 1,3-dimethyl-5-*tert*-butylbenzene, and nitration of the resulting 2,6-dimethyl-4-*tert*-butylacetophenone with nitric acid.

Musk ketone

Musk ketone is widely used as a fixative in blossom and phantasy compositions.

Cinnamonitrile [*4360-47-8*], C_9H_7N, M_r 129.16, *bp* (1.7 kPa) 135 – 135.5 °C, *mp* 23.5 – 24 °C, d^{25} 1.0244, n_D^{25} 1.6001; *trans*-cinnamonitrile is a colorless crystalline solid or a colorless viscous liquid with a spicy, slightly flowery odor.

Cinnamonitrile can be prepared by one of the common routes to nitriles, e.g., by dehydration of cinnamaldoxime. It is stable to alkali and is used for perfuming soap and detergents.

Trade Name. Cinnamalva (IFF).

5-Phenyl-3-methyl-2-pentenonitrile [*93893-89-1*], $C_{12}H_{13}N$, M_r 171.24, *bp* (20 Pa) 82 – 88 °C, d^{25} 0.979, n_D^{20} 1.5340, is a colorless liquid with a citrus-fruity, slightly balsamic odor. The commercial product is a 2 : 3 mixture of the *cis* and *trans*-isomers.

The nitrile is prepared by condensation of benzylacetone with cyanoacetic acid in the presence of pyridine and by elimination of carbon dioxide. The mixture is used as such in soap and detergent perfumes [140].

Trade Name. Citronitril (Haarmann & Reimer).

Methyl anthranilate [*134-20-3*], $C_8H_9NO_2$, M_r 151.16, *bp* (2 kPa) 135.5 °C,

mp 24 – 25 °C, d_4^{19} 1.1682, n_D^{20} 1.5815, occurs in a large number of blossom essential oils (e.g., neroli, ylang-ylang, and jasmin oils), grapes, and citrus oils. It occurs as white crystals or a yellowish liquid, that show blue fluorescence and have an orange blossom odor. Methyl anthranilate is prepared by esterification of anthranilic acid with methanol or by reaction of isatoic anhydride with methanol [141].

Methyl anthranilate

It is used in a large number of blossom fragrances. However, its use in perfumes for soaps and cosmetics is limited because it causes discoloration. It is used in aroma compositions (e.g., in grape and citrus flavors).

Methyl *N*-methylanthranilate [*85-91-6*], $C_9H_{11}NO_2$, M_r 165.19, *bp* (1.6 kPa) 130 – 131 °C, d_4^{20} 1.1295, n_D^{20} 1.5796, is the main component of petitgrain oil from mandarin leaves and is also found in mandarin peel oil. It is a pale yellow, fluorescent liquid with a delicate mandarin odor. The ester can be prepared by methylation of methyl anthranilate. It is used in soap and cosmetic perfumes as well as in aromas, particularly for mandarin flavors. (IFRA recommendation)

Some Schiff's bases of methyl anthranilate are interesting fragrance materials, e.g., those formed with hydroxydihydrocitronellal [*89-43-0*] and 2,4-dimethyl-3-cyclohexene carboxaldehyde [*68845-02-3*]. Both have a heavy blossom odor and a high tenacity.

2.6. Phenols and Phenol Derivatives

For a detailed description of phenols and their derivatives, see → Phenol, → Phenol Derivatives.

2.6.1. Phenols, Phenyl Esters, and Phenyl Ethers

Of the phenols and phenyl ethers used as fragrance and flavor compounds, 4-allyl- (**30**, R = H) and 4-propenylphenols (**31** and **32**, R = H) and their methyl ethers (**30** – **32**, R = CH_3) occur particularly frequently in essential oils.

30 **31** **32**

A second hydroxyl or methoxyl substituent is often present; 2-methoxy-4-allylphenol and 2-methoxy-4-propenylphenol are the most important compounds belonging to this category.

Diphenyl ether [*101-84-8*], $C_{12}H_{10}O$, M_r 170.21, *bp* (1.34 kPa) 121 °C, *mp* 26.8 °C, d^{20} 1.0748, has not been observed in nature. It is a colorless liquid or a crystalline solid with an odor reminiscent of geranium leaves. Diphenyl ether is obtained as a byproduct in the production of phenol by high-pressure hydrolysis of chlorobenzene. For further details of properties and synthesis, see → Phenol Derivatives, Chap. 6.3. Because of its stability and low price, diphenyl ether is used in large quantities in soap perfumes. However, its main application is as a heat-transfer medium (eutectic mixture with diphenyl).

Thymol [*89-83-8*], 2-isopropyl-5-methylphenol, $C_{10}H_{14}O$, M_r 150.22, *bp* (101.3 kPa) 232.5 °C, *mp* 51.5 °C, d_4^{20} 0.9756, n_D^{20} 1.5227, is the main constituent of thyme and some origanum oils; it also occurs in many other essential oils. It forms colorless crystals with a spicy-herbal, slightly medicinal odor reminiscent of thyme. For further details of properties and synthesis, see → Phenol Derivatives, Chap. 1.5.3.

Thymol is used as a dry top note in lavender compositions, in men's fragrances, and as a disinfectant in oral hygiene products. It is also important as a starting material for the production of racemic menthol (see page 30).

Anethole [*104-46-1*], 1-methoxy-4-propenylbenzene, $C_{10}H_{12}O$, M_r 148.20, *trans*-isomer: *bp* °C, d_4^{20} 0.9883, n_D^{20} 1.5615, occurs both as its *cis*- and *trans*-isomers in nature; however, *trans*-anethole is always the main isomer. Anethole occurs in anise oil (80–90 %), star anise oil (> 90 %), and fennel oil (80 %).

trans-Anethole [*4180-23-8*] forms colorless crystals (*mp* 21.5 °C) with an anise-like odor and a sweet taste. Anethole is oxidized to anisaldehyde (e.g., with chromic acid); when hydrogenated it is converted into 1-methoxy-4-propylbenzene.

Production. Isolation of anethole from anethole-rich essential oils has lost its significance in favor of isolation from sulfate turpentine oils (see page 118).

1) Anethole can be crystallized from oils in which it occurs as a major component (anise, star anise, and fennel oils).
2) A fraction of American sulfate turpentine oil (0.5 % of the total) consists mainly of an azeotropic mixture of anethole and caryophyllene. *trans*-Anethole can be isolated from this mixture by crystallization.
3) Another fraction of American sulfate turpentine oil (1 % of the total) consists essentially of an azeotropic mixture of estragole (1-methoxy-4-allylbenzene, *bp* (101.3 kPa) 216 °C) and α-terpineol. Treatment with potassium hydroxide yields a mixture of anethole isomers and α-terpineol, which can be separated by fractional distillation.

Estragole Anethole

Since isolation from oils does not always satisfy demand, synthetic processes starting from anisole have been developed.

4) *Synthesis from Anisole and Propionic Acid Derivatives.* Anisole is converted into 4-methoxypropiophenone by Friedel–Crafts acylation with propionyl chloride or propionic anhydride. The ketone is hydrogenated to the corresponding alcohol with a copper chromite catalyst. The alcohol is dehydrated in the presence of acidic catalysts to a mixture of *cis*- and *trans*-anethole [142].

Anisole Anethole

5) *Synthesis from Anisole and Propanal.* Anisole is converted into a mixture of 1,1-bis(4-methoxyphenyl)propane and small amounts of isomeric compounds by condensation with propionaldehyde in the presence of catalytic amounts of acid. 1,1-Bis(4-methoxyphenyl) propane is cleaved when heated to give anethole and anisole [143].

Uses. Anethole is used in large quantities in the alcoholic beverage industry (Pernod, Ouzo) and in oral hygiene products. Some crude anethole is converted into anisaldehyde.

2-Phenoxyethyl isobutyrate [*103-60-6*], $C_{12}H_{16}O_3$, M_r 208.26, *bp* (530 Pa) 125–127 °C, d_{25}^{25} 1.044–1.050, n_D^{20} 1.492–1.496, is a fragrance compound that does not occur in nature. It is a colorless liquid with a sweet, flowery-fruity odor.

The ester is prepared by esterification of 2-phenoxyethanol with isobutyric acid and is used as a fixative in perfumes (rose and lavender types) as well as for fruity notes.
Trade Name. Phenirat (Haarmann & Reimer).

β-Naphthyl Alkyl Ethers. The β-naphthyl alkyl ethers described below are used in perfumery, especially in soap perfumes. The ethers are prepared by O-alkylation of β-naphthol. They have not been observed in nature.

β-Naphthyl methyl ether [*93-04-9*], R = CH_3, $C_{11}H_{10}O$, M_r 158.20, *bp* (1.3 kPa) 138 °C, *mp* 73 – 74 °C, forms white crystals with an intense orange blossom odor.

β-Naphthyl ethyl ether [*93-18-5*], R = CH_2CH_3, $C_{12}H_{12}O$, M_r 172.23, *bp* (1.3 kPa) 148 °C, *mp* 37 – 38 °C, forms white crystals with a mild, long-lasting, orange blossom fragrance.

β-Naphthyl isobutyl ether [*2173-57-1*], R = $CH_2CH(CH_3)_2$, $C_{14}H_{16}O$, M_r 200.28, *mp* 33 – 33.5 °C, forms white crystals with a fruity, orange blossom odor.

Hydroquinone dimethyl ether [*150-78-7*], 1,4-dimethoxybenzene, $C_8H_{10}O_2$, M_r 138.17, *bp* (2.7 kPa) 109 °C, *mp* 57 – 58 °C, occurs in hyacinth oil and has also been identified in tea. It is a white crystalline solid with an intensely sweet, somewhat herbal, nutlike odor.

Hydroquinone dimethyl ether is prepared by etherification of hydroquinone and is used in soap perfumes.

Isoeugenol [*97-54-1*], 2-methoxy-4-(1-propenyl)phenol, $C_{10}H_{12}O_2$, M_r 164.22; *cis*-isomer [*5912-86-7*]: *bp* (1.7 kPa) 134 – 135 °C, d_4^{20} 1.0837, n_D^{20} 1.5726; *trans*-isomer [*5932-68-3*]: *mp* 33 – 34 °C, *bp* (1.7 kPa) 141 – 142 °C, d_4^{20} 1.0852, n_D^{20} 1.5784. Isoeugenol occurs in many essential oils, mostly with eugenol, but not as the main component. Commercial isoeugenol is a mixture of *cis*- and *trans*-isomers, in which the *trans*-isomer dominates because it is thermodynamically more stable. Isoeugenol is a yellowish, viscous liquid with a fine clove odor, that of the crystalline *trans*-isomer being the more delicate.

Isoeugenol can be hydrogenated catalytically to form dihydroeugenol. Vanillin was formerly prepared by oxidation of isoeugenol. Additional fragrance compounds are prepared by esterification or etherification of the hydroxyl group.

Production. Starting materials for the synthesis of isoeugenol are eugenol and guaiacol.

1) *Synthesis from Eugenol.* The sodium or potassium salt of eugenol is isomerized to isoeugenol by heating. Isomerization can also be carried out catalytically in the presence of ruthenium [144] or rhodium [145] compounds.

Eugenol Isoeugenol

2) *Synthesis from Guaiacol.* Guaiacol is esterified with propionic acid, and the resulting guaiacyl propionate rearranges in the presence of aluminum chloride to give 4-hydroxy-3-methoxypropiophenone. Reduction of the ketone to the corresponding secondary alcohol and dehydration finally yield isoeugenol [146–148].

Guaiacol

Uses. Isoeugenol is used in perfumery in a large number of blossom compositions, mostly for clove and carnation types, but also in oriental perfumes. (Limiting IFRA recommendation)

Small amounts are employed in aromas and in reconstituted essential oils.

Isoeugenol methyl ether [*93-16-3*], $C_{11}H_{14}O_2$, M_r 178.23, *cis*-isomer [*6380-24-1*]: *bp* (900 Pa) 137 – 137.5 °C, d_4^{20} 1.0530, n_D^{20} 1.5628; *trans*-isomer [*6379-72-2*]: *bp* (700 Pa) 126 °C, d_4^{20} 1.0556, n_D^{20} 1.5699, occurs in small quantities in several essential oils. It is a colorless to pale yellow liquid with a mild clove odor.

Isoeugenol methyl ether is used in perfumery in clove and carnation bases and as a fixative in spicy-floral compositions.

Eugenol [*97-53-0*], 2-methoxy-4-allylphenol, $C_{10}H_{12}O_2$, M_r 164.20, *bp* (1.3 kPa) 121 °C, d_4^{20} 1.0652, n_D^{20} 1.5409, is the main component of several essential oils; clove leaf oil and cinnamon leaf oil may contain > 90 %. Eugenol occurs in small amounts in many other essential oils. It is a colorless to slightly yellow liquid with a spicy, clove odor.

Catalytic hydrogenation (e.g., in the presence of noble-metal catalysts) yields dihydroeugenol. Isoeugenol is obtained from eugenol by shifting the double bond (see Isoeugenol, page 65). Esterification and etherification of the hydroxyl group of eugenol yield valuable fragrance and flavor materials (e.g., eugenyl acetate and eugenyl methyl ether).

Production. Since sufficient eugenol can be isolated from cheap essential oils, synthesis is not industrially important. Eugenol is still preferentially isolated from clove leaf and cinnamon leaf oil (e.g., by extraction with sodium hydroxide solution). Nonphenolic materials are then removed by steam distillation. After the alkaline solution is acidified at low temperature, pure eugenol is obtained by distillation.

Uses. Eugenol is used in perfumery in clove and carnation compositions as well as for oriental and spicy notes. It is a common component of clove and other aroma compositions. In dentistry, it is used as an antiseptic.

Eugenol methyl ether [*93-15-2*], $C_{11}H_{14}O_2$, M_r 178.23, *bp* (1.5 kPa) 127 – 129 °C, d_4^{20} 1.0396, n_D^{20} 1.5340, occurs in numerous essential oils, sometimes at a very high concentration; leaf and wood oil from *Dacrydium franklinii* Hook. (Huon pine oil) contain more than 90 %. The ether is an almost colorless liquid with a mild-spicy, slightly herbal odor. It is prepared by methylation of eugenol and is used in perfumery (e.g., in carnation and lilac compositions) and in flavor compositions.

Eugenyl acetate [*93-28-7*], $C_{12}H_{14}O_3$, M_r 206.24, *bp* (400 Pa) 120 – 121 °C, *mp* 29 °C, d_4^{20} 1.0806, n_D^{20} 1.5205, occurs in clove oil, together with eugenol. It is a crystalline solid or yellowish liquid with a slightly fruity, clove odor. Eugenyl acetate is prepared by acetylation of eugenol with acetic anhydride and is used in clove compositions to accentuate flowery character.

Propenylguethol [*94-86-0*], 2-ethoxy-5-(1-propenyl)phenol, $C_{11}H_{14}O_2$, M_r 178.23, exists in *cis* (*mp* 35 – 36 °C) and in *trans* (*mp* 86 °C) forms. The *trans*-isomer has a sweet vanilla-like odor. Propenylguethol can be prepared from isosafrole by reaction with methylmagnesium chloride or by ethylation of isoeugenol followed by selective demethylation with alkali [149].

It is used in perfumery, for example, in soaps and cosmetics, to create or enhance vanilla notes.

***p*-Cresyl phenylacetate** [*101-94-0*], $C_{15}H_{14}O_2$, M_r 226.27, is prepared by esterification of *p*-cresol with phenylacetic acid. It forms crystals (*mp* 75 – 76 °C) with a narcissus odor and a honey note. It is used in blossom compositions with a slight animal note.

2.6.2. Phenol Alcohols and their Esters

In comparison with the araliphatic alcohols discussed in Section 2.5.5, very few phenol alcohols are used as fragrance and flavor materials. None of the alcohol derivatives of vanillin, ethylvanillin, and heliotropin or their esters have special organoleptic properties. Anise alcohol and its acetate are the only products that are used to some extent in perfume and aroma compositions.

Anisyl alcohol [*105-13-5*], 4-methoxybenzyl alcohol, $C_8H_{10}O_2$, M_r 138.17, *bp* (1.3 kPa) 136 °C, d_4^{20} 1.1140, n_D^{25} 1.5420, occurs in vanilla pods and in anise seeds. It is a colorless liquid with a sweet-flowery, slightly balsamic odor.

Pure anise alcohol for perfumery and flavor purposes is prepared by hydrogenation of anisaldehyde. It is used in perfumery in blossom compositions (e.g., lilac and gardenia types) and in flavors for confectionery and beverages.

Anisyl acetate [*104-21-2*], $C_{10}H_{12}O_3$, M_r 180.20, *bp* (1.5 kPa) 133 °C, d_4^{20} 1.1084, has been found in several types of berries. It is a colorless liquid with a fruity, slightly balsamic blossom odor and is used occasionally in sweet-flowery compositions, but more frequently in flavor compositions for fruity notes.

2.6.3. Phenol Aldehydes

Phenol aldehydes are generally pleasant-smelling products. Some of them are particularly important as fragrance and flavor compounds. Anisaldehyde and certain derivatives of protocatechu aldehyde (3,4-dihydroxybenzaldehyde) are well-known representatives. The monomethyl ether of protocatechu aldehyde, vanillin, is perhaps the most widely used flavor compound. Other important derivatives of this aldehyde are veratraldehyde (dimethyl ether) and piperonal (formaldehyde acetal derivative); they are not only used as fragrance and flavor substances, but also are intermediates in many industrial processes.

***p*-Anisaldehyde** [*123-11-5*], 4-methoxybenzaldehyde, $C_8H_8O_2$, M_r 136.15, *bp* (1.85 kPa) 132 °C, d_4^{25} 1.1192, n_D^{25} 1.5703, occurs in many essential oils, often together with anethole. It is a colorless to slightly yellowish liquid with a sweet, mimosa, hawthorn odor. *p*-Anisaldehyde can be hydrogenated to anise alcohol and readily oxidizes to anisic acid when exposed to air. Synthetic routes to anisaldehyde usually involve the oxidation of *p*-cresyl methyl ether. Manganese dioxide and sulfuric acid are usually used for oxidation. In a Russian process, *p*-cresyl methyl ether is oxidized with alkali peroxysulfates in the presence of silver salts [150].

p-Anisaldehyde

Other industrial processes are the liquid-phase oxidation in the presence of cobalt catalysts [151] and the electrochemical oxidation in the presence of lower aliphatic alcohols via the corresponding anisaldehyde dialkyl acetal [152].

p-Anisaldehyde is frequently used in sweet blossom compositions (e.g., in lilac and hawthorn types) as well as in flavor compositions for confectioneries and beverages. *p*-Anisaldehyde is an intermediate in many industrial processes. Its hydrogensulfite derivative is used as a brightener for metals in galvanic baths.

Vanillin [*121-33-5*], 4-hydroxy-3-methoxybenzaldehyde, $C_8H_8O_3$, M_r 152.15, *bp* (1.3 kPa) 155 °C, *mp* 82 – 83 °C, d_4^{20} 1.056, is found in many essential oils and foods, but is often not essential for their odor or aroma. However, it does determine the odor of essen-

tial oils and extracts from *Vanilla planifolia* and *V. tahitensis* pods, in which it is formed during ripening by enzymatic cleavage of glycosides.

Annually about 12 000 t vanillin are produced synthetically and about 20 t originate from natural sources [153].

Properties. Vanillin is a colorless crystalline solid with a typical vanilla odor. Because it possesses aldehyde and hydroxyl substituents, it undergoes many reactions. Additional reactions are possible due to the reactivity of the aromatic nucleus. Vanillyl alcohol and 2-methoxy-4-methylphenol are obtained by catalytic hydrogenation; vanillic acid derivatives are formed after oxidation and protection of the phenolic hydroxyl group. Since vanillin is a phenol aldehyde, it is stable to autoxidation and does not undergo the Cannizzaro reaction. Numerous derivatives can be prepared by etherification or esterification of the hydroxyl group and by aldol condensation at the aldehyde group. For example, several of these derivatives are intermediates in the synthesis of pharmaceuticals.

Production. Most commercial vanillin is obtained by processing waste sulfite liquors; the remainder is synthesized from guaiacol. Preparation by oxidation of isoeugenol is of historical interest only.

Preparation from Waste Sulfite Liquors:
The starting material for vanillin production is the lignin present in sulfite wastes from the cellulose industry (→ Lignin). The concentrated mother liquors are treated with alkali at elevated temperature and pressure in the presence of oxidants. The vanillin formed is separated from the byproducts, particularly acetovanillone (4-hydroxy-3-methoxyacetophenone), by extraction, distillation, and crystallization.
A large number of patents describe various procedures for the (mainly) continuous hydrolysis and oxidation processes, as well as for the purification steps required to obtain high-grade vanillin [154]. Lignin is degraded either with sodium hydroxide or with calcium hydroxide solution and simultaneously oxidized in air in the presence of catalysts. When the reaction is completed, the solid wastes are removed. Vanillin is extracted from the acidified solution with a solvent (e.g., butanol or benzene) and reextracted with sodium hydrogen sulfite solution. Reacidification with sulfuric acid followed by vacuum distillation yields technical-grade vanillin, which must be recrystallized several times to obtain food-grade vanillin. Water, to which some ethanol may be added, is used as the solvent in the last crystallization step.

Preparation from Guaiacol and Glyoxylic Acid.
Several methods can be used to introduce an aldehyde group into an aromatic ring. Condensation of guaiacol with glyoxylic acid followed by oxidation of the resulting mandelic acid to the corresponding phenylglyoxylic acid and, finally, decarboxylation continues to be a competitive industrial process for vanillin synthesis.
Currently, guaiacol is synthesized from catechol, which is prepared by acid-catalyzed hydroxylation of phenol with hydrogen peroxide. Glyoxylic acid is obtained as a byproduct in the synthesis of glyoxal from acetaldehyde and can also be produced by oxidation of glyoxal with nitric acid. Condensation of guaiacol with glyoxylic acid proceeds smoothly at room temperature and in weakly alkaline media. A slight excess of guaiacol is maintained to avoid formation of disubstituted products; excess guaiacol is recovered. The alkaline solution containing 4-hydroxy-3-methoxymandelic acid is then oxidized in air in the presence of a catalyst until the calculated amount of oxygen is consumed [155]. Crude vanillin is obtained by acidification and simultaneous decarboxylation of the (4-hydroxy-3-methoxyphenyl) glyoxylic acid solution. Commercial grades are obtained by vacuum distillation and subsequent recrystallization as described under method (1).
This process has the advantage that, under the reaction conditions, the glyoxyl radical enters the aromatic guaiacol ring almost exclusively para to the phenolic hydroxyl group. Tedious separation procedures are thus avoided.

Uses. The main application of vanillin is the flavoring of foods (e.g., ice cream, chocolate, bakery products, and confectioneries). Small quantities are used in perfumery to round and fix sweet, balsamic fragrances. Vanillin is also used as a brightener in galvanotechnical processes and is an important intermediate in, for example, the production of pharmaceuticals such as L-3,4-dihydroxyphenylalanine (L-DOPA) and methyldopa.

Veratraldehyde [*120-14-9*], 3,4-dimethoxybenzaldehyde, $C_9H_{10}O_3$, M_r 166.18, occurs in a few essential oils and is a crystalline solid (*mp* 44.5 – 45 °C) with a woody, vanilla-like odor.

Veratraldehyde can be prepared by methylation of vanillin. It is used in oriental and warm-woody fragrances, as well as in flavor compositions for vanilla notes. It is an intermediate in, for example, the synthesis of pharmaceuticals.

Ethylvanillin [*121-32-4*], 3-ethoxy-4-hydroxybenzaldehyde, $C_9H_{10}O_3$, M_r 166.18, *mp* 77 – 78 °C, does not occur in nature. Its odor resembles that of vanillin but is approximately three times as strong. Ethylvanillin can be prepared by method (2) as described for vanillin, using guethol instead of guaiacol as the starting material.

Ethylvanillin is used extensively in the chocolate industry. It gives a sweet, balsamic note to flowery and fruity perfume compositions.

Piperonal [*120-57-0*], heliotropin, 3,4-methylenedioxybenzaldehyde, $C_8H_6O_3$, M_r 150.13, *bp* (1.6 kPa) 139.4 °C, *mp* 37 °C, $d_4^{43.2}$ 1.2792, occurs in a number of essential oils, but never as the main component. It forms white crystals with a sweet-flowery, slightly spicy, heliotrope-like odor.

Production. Piperonal is produced by two main routes:

From Isosafrole.
For many years, oxidative cleavage of isosafrole was the only route applicable on an industrial scale. Examples of oxidants that give good yields of piperonal are chromium(VI) salts, oxygen, and ozone.

This method is still used currently because safrole (the starting material for isosafrole) can be isolated from essential oils relatively inexpensively and in sufficient quantity.

From Catechol. Several routes have been developed for the synthesis of piperonal from catechol. In one such route, catechol is converted into 3,4-dihydroxymandelic acid with glyoxylic acid in an alkaline medium in the presence of aluminum oxide. 3,4-Dihydroxymandelic acid is oxidized to the corresponding keto acid (e.g., with copper(II) oxide), which is decarboxylated to 3,4-dihydroxybenzaldehyde [156]. The latter product is converted into piperonal, for

example, by reaction with methylene chloride in the presence of quaternary ammonium salts [157].

In another route, catechol is first reacted with methylene chloride and converted into 1,2-methylenedioxybenzene [157]. Reaction with glyoxylic acid in strongly acidic media yields 3,4-methylenedioxymandelic acid [158]. Subsequent oxidation and decarboxylation with nitric acid affords piperonal.

Uses. Piperonal is used in many flowery-spicy fine fragrances and is also an important ingredient of flavor compositions.

2.6.4. Phenol Ketones

Few of the phenol derivatives that have a keto substituent in their side-chain are of interest as fragrance or flavor substances. A number of phenols and phenyl ethers acetylated in the benzene ring have been identified as volatile components of foods. 4-Methoxyacetophenone is of some interest as a fragrance compound. 4-Hydroxybenzylacetone, a higher mass phenol ketone, has a characteristic raspberry aroma.

4-Methoxyacetophenone [*100-06-1*], acetanisole, $C_9H_{10}O_2$, M_r 150.18, d^{41} 1.0818, n_D^{41} 1.5470, occurs in anise oil. It forms white crystals (*mp* 38 °C) with a sweet odor, reminiscent of hawthorn. 4-Methoxyacetophenone is prepared by Friedel–Crafts acetylation of anisole and is used in soap perfumes.

1-(4-Hydroxyphenyl)-3-butanone [*5471-51-2*], raspberry ketone, $C_{10}H_{12}O_2$, M_r 164.20, *mp* 82 – 83 °C, is a highly characteristic component of raspberry aroma. It forms colorless crystals with a sweet-fruity odor strongly reminiscent of raspberries.

Raspberry ketone is prepared by alkali-catalyzed condensation of the alkali salt of 4-hydroxybenzaldehyde and acetone, followed by selective hydrogenation of the double bond in the resulting 4-hydroxybenzalacetone. Other syntheses start from phenol which is converted into 1-(4-hydroxyphenyl)-3-butanone with methyl vinyl ketone (e.g., in the presence of phosphoric acid) [159] or with 3-oxo-1-butanol in the presence of concentrated sulfuric acid [160].

The ketone is used in fruit flavors, particularly in raspberry compositions.

Trade Names. Frambinon (DRAGOCO), Oxyphenylon (IFF).

2.6.5. Phenol Carboxylates

Alkyl and aralkyl salicylates, as well as methyl 3-methylorsellinate (an oakmoss fragrance) are important phenol carboxylates that are used in flavors and fragrances. The following salicylates are used in perfume and flavor compositions and can be prepared by esterification of salicylic acid.

Methyl salicylate [*119-36-8*], R = CH_3, $C_8H_8O_3$, M_r 152.15, *bp* (1.6 kPa) 98 °C, d_4^{25} 1.1782, n_D^{25} 1.5350, is the main component of wintergreen oil and occurs in small quantities in other essential oils and fruit. It is a colorless liquid with a sweet, phenolic odor. Methyl salicylate is used in perfumery as a modifier in blossom fragrances and as a mild antiseptic in oral hygiene products.

Isoamyl salicylate [*87-20-7*], R = $CH_2CH_2CH(CH_3)_2$, $C_{12}H_{16}O_3$, M_r 208.26, *bp* (2 kPa) 151 – 152 °C, d_4^{20} 1.0535, n_D^{20} 1.5065, has been found in a number of fruit aromas. It is a colorless liquid with a sweet, clover-like odor and is used in perfumery for floral and herbal notes, particularly in soap perfumes.

Hexyl salicylate [*6259-76-3*], R = $(CH_2)_5CH_3$, $C_{13}H_{18}O_3$, M_r 222.28, *bp* (1.6 kPa) 167 – 168 °C, d_{25}^{25} 1.035, n_D^{25} 1.5049, has been reported in carnation flower absolute [161]. It is a colorless liquid with a green, flowery-spicy odor, reminiscent of azaleas. It is used for blossom and herbal notes in perfumes, e.g., in soap, personal hygiene products, and detergents.

***cis*-3-Hexenyl salicylate** [*65405-77-8*], R = *cis*-$(CH_2)_2CH{=}CHCH_2CH_3$, $C_{13}H_{16}O_3$, M_r 220.27, *bp* (150 Pa) 125 °C, d_{25}^{25} 1.0589, n_D^{20} 1.5210, has been identified in carnation flower absolute. It is a colorless liquid with a long-lasting, sweet, green balsamic odor. It is used in fine fragrances and for scenting soaps, cosmetics, and detergents.

Benzyl salicylate [*118-58-1*], R = $CH_2C_6H_5$, $C_{14}H_{12}O_3$, M_r 228.25, *bp* (1.3 kPa) 186 – 188 °C, d_4^{20} 1.1799, n_D^{20} 1.5805, which occurs in several essential oils, is a colorless, viscous liquid with a weak, sweet, slightly balsamic odor. Benzyl salicylate is used as a fixative in flowery-spicy perfume compositions and in flavors.

Phenethyl salicylate [*87-22-9*], R = $CH_2CH_2C_6H_5$, $C_{15}H_{14}O_3$, M_r 242.27, *mp* 44 °C, which has not been reported to occur in nature, is a crystalline solid with a weak, long-lasting, balsamic, blossom odor, reminiscent of rose and hyacinth. It is used in perfumery for spicy and balsamic blossom compositions.

Methyl 3-methylorsellinate [*4707-47-5*], methyl 2,4-dihydroxy-3,6-dimethylbenzoate, $C_{10}H_{12}O_4$, M_r 196.20, *mp* 145 °C, is an odor-determining constituent of oakmoss extract and forms colorless crystals with a mossy-earthy odor. It can be prepared from acyclic compounds. In an industrial process, dimethyl malonate is condensed with 4-hexen-3-one (or a mixture of this ketone and 5-chlorohexan-3-one) to give a substituted 3-hydroxy-2-cyclohexenone (**33**). Aromatization, in good yield, is achieved by reaction of the hydroxycyclohexenone with a suitable *N*-haloamide. The intermediate 3-hydroxy-2-cyclohexenone can also be obtained by condensation of methyl 3-oxopentanoate with methyl crotonate [162].

Another route to methyl 3-methylorsellinate starts from β-orcinol, which is converted into a carboxylic acid derivative by reaction with carbon dioxide (Kolbe synthesis). The acid is esterified (e.g., with dimethyl sulfate) [163].

Methyl 3-methylorsellinate is used as a substitute for oakmoss extract in fine fragrances, soaps, and cosmetics.

Trade Name. Evernyl (Givaudan Roure), Veramoss (IFF).

2.7. O- and O, S-Heterocycles

2.7.1. Cyclic Ethers

Cyclic ethers used as fragrances include a number of terpenoid compounds. Some of them, such as 1,4-cineole [*470-67-7*] and 1,8-cineole, occur in essential oils in significant quantities. Others are only minor components; examples are rose oxide, nerol oxide [*1786-08-9*], and rose furan [*15186-51-3*], which contribute to the specific fragrance of rose oil, and caryophyllene oxide [*1139-30-6*], which has a woody, slightly ambergris-like odor. α-Cedrene oxide [*11000-57-0*] is another wood-fragrance compound, that can be easily prepared by epoxidation of cedarwood oil hydrocarbons.

Except for some of the above-mentioned compounds, only a few other cyclic ethers are important, for instance, 4,6,6,7,8,8-hexamethyl-1,3,4,6,7,8-hexahydropenta[*g*]benzopyran, a musk fragrance that is used in large amounts.

Numerous furan and pyran derivatives, many of which originate from heat treatment of carbohydrates, largely determine the odor of processed foods. Of this group, 2,5-dimethyl-4-hydroxy-2*H*-furan-3-one and maltol are used in fairly large quantities in flavors. The following compounds are used in relatively small amounts in flavor compositions:

2-Furaldehyde [*98-01-1*], freshyl baked bread odor

2-Acetylfuran [*1192-62-7*], sweet balsamic odor

Methyl 2-furoate [*611-13-2*], fruity, mushroom-like odor

2-Methylfuran-3-thiol [*28588-74-1*], roast beef aroma

2,5-Diethyltetrahydrofuran [*41239-48-9*], fruity, herbal-minty note

2-Methyl-4-propyl-1,3-oxathiane [*67715-80-4*], typical sulfury note of tropical fruit

1,8-Cineole [*470-82-6*], 1,8-epoxy-*p*-menthane, eucalyptol, $C_{10}H_{18}O$, M_r 154.25, *bp* (101.8 kPa) 176 – 177 °C, *fp* 1 °C, d_4^{20} 0.9267, n_D^{20} 1.4586, occurs in many terpene-containing essential oils, sometimes as the main component. For example, eucalyptus oils contain up to 85 % 1,8-cineole and laurel leaf oil contains up to 70 %. It is a colorless liquid with a characteristic odor, slightly reminiscent of camphor.

1,8-Cineole is one of the few fragrance materials that is obtained exclusively by isolation from essential oils, especially eucalyptus oils. Technical-grade 1,8-cineole with a purity of 99.6 – 99.8 % is produced in Spain in large quantities by fractional distillation of *Eucalyptus globulus* Labillardière. A product essentially free from other products can be obtained by crystallization of cineole-rich eucalyptus oil fractions.

1,8-Cineole has a fresh odor and is used in large quantities in fragrances as well as in flavors (e.g., in oral hygiene products).

4-Methyl-2-(2-methyl-1-propenyl)tetrahydropyran [*16409-43-1*], rose oxide, $C_{10}H_{18}O$, M_r 154.25, *bp* (1.6 kPa) 70 °C, d_4^{20} 0.875, n_D^{20} 1.4570, $[\alpha]_D$ for the optically pure (−)-*cis* form − 58.1 °, occurs in small quantities, mainly the levorotatory *cis* form, in essential oils (e.g., Bulgarian rose oil and geranium oil). Commercial synthetic products are either optically active or inactive mixtures of the *cis*- and

trans-isomers. Their physical constants, particularly the optical rotation, depend on the starting material and the method of synthesis. They are colorless liquids with a strong odor reminiscent of geranium oil and carrot leaves. Rose oxide is usually prepared from citronellol (see page 19), which can be converted into a mixture of two allyl hydroperoxides (e.g., by photosensitized oxidation with oxygen). Reduction of the hydroperoxides with sodium sulfite yields the corresponding diols [164]. Treatment with dilute sulfuric acid results in allylic rearrangement and spontaneous cyclization of one of the isomers; a mixture of diastereoisomeric rose oxides is thus formed. The unreacted diol isomer is separated by distillation. (−)-Citronellol as the starting material yields approximately a 1 : 1 mixture of (−)-*cis*- and (−)-*trans*-rose oxide.

(−)-Citronellol

(−)-*cis*-
Rose oxide

(−)-*trans*-
Rose oxide

Rose oxide is used in rose and geranium perfumes.

Trade Name. Rose oxide (DRAGOCO).

Menthofuran [*494-90-6*], 3,6-dimethyl-4,5,6,7-tetrahydrobenzofuran, $C_{10}H_{14}O$, M_r 150.22, *bp* (1.3 kPa) 78 – 79 °C, d_4^{20} 0.9676, n_D^{20} 1.4855, $[\alpha]_D^{20}$ +94.6 °, occurs mainly as the (+)-isomer, in numerous essential oils (e.g., Mentha oils). It is a colorless liquid with a minty odor.

(+)-Menthofuran [*17957-94-7*] is isolated from Mentha oils or is prepared synthetically, for example, by treatment of (+)-pulegone with fuming sulfuric acid in acetic anhydride and pyrolysis of the resulting sultone.

(+)-Pulegone

Menthofuran

Menthofuran is used mainly in peppermint oil reconstitutions.

Linalool oxide, 2-methyl-2-vinyl-5-(α-hydroxyisopropyl)tetrahydrofuran, $C_{10}H_{18}O_2$, M_r 170.25, *bp* (101.3 kPa) 188 °C, d_4^{20} 0.939 – 0.944, n_D^{20} 1.451 – 1.455, has been identified in essential oils and in fruit aromas. Commercial linalool oxide is a mixture of the *cis* and *trans* forms, [*5989-33-3*] and [*34995-77-2*], respectively. It is a liquid with an earthy-flowery, slightly bergamot-like odor.

Linalool oxide

Linalool oxide is prepared by oxidation of linalool (see page 16). The isomeric compound 2,2,6-trimethyl-6-vinyltetrahydro-2*H*-pyran-3-ol [*14049-11-7*], which also occurs in nature, is formed as a byproduct:

Linalool oxide is used in perfumery (e.g., for lavender notes) and for reconstitution of essential oils.

A dehydrated linalool oxide, 2-methyl-2-vinyl-5-isopropenyltetrahydrofuran [*13679-86-2*], occurs naturally; it has a minty eucalyptol odor and is used in perfumery.

3a,6,6,9a-Tetramethyldodecahydronaphtho-[2,1-*b*]furan [*6790-58-5*] (**34**), $C_{16}H_{28}O$, M_r 236.40, *mp* 75 – 76 °C, is a crystalline autoxidation product of ambrein (see Ambergris, page 87) with a typical ambergris odor. It is prepared from sclareol, a diterpene alcohol obtained from plant waste in the production of clary sage oil (see Sage Oils, page 115). Oxidative degradation to a lactone, hydrogenation of the latter to the corresponding diol and dehydration yield (**34**).

The product is used in perfumery for creating ambergris notes.

Trade Names. Ambrox (Firmenich), Ambroxan (Cognis).

2,5-Dimethyl-4-hydroxy-2*H*-furan-3-one [*3658-77-3*], $C_6H_8O_3$, M_r 128.13, is a constituent of pineapple aroma and is also found in other foods. It forms colorless crystals (*mp* 77 – 79 °C) with a relatively weak, nonspecific odor. Dilute solutions develop a pineapple, strawberry-like odor. It can be prepared by cyclization of hexane-2,5-diol-3,4-dione in the presence of an acidic catalyst [165]. The dione is the ozonization product of 2,5-hexynediol, which is obtained by ethynylation of acetaldehyde.

2,5-Dimethyl-4-hydroxy-2*H*-furan-3-one

In another process, a dialkyl α-methyldiglycolate (formed from an alkyl lactate and an alkyl monochloroacetate) is reacted with dialkyl oxalate in the presence of a sodium alkoxide and dimethylformamide. The reaction product is cyclized, alkylated, hydrolyzed, and decarboxylated [166].

The compound is used in the flavoring of foods.

Trade Name. Furaneol (Firmenich).

Maltol [*118-71-8*], 3-hydroxy-2-methyl-4*H*-pyran-4-one, $C_6H_6O_3$, M_r 126.11, *mp* 162 – 164 °C, occurs in pine needles and the bark of young larch trees. It is produced when cellulose or starch are heated and is a constituent of wood tar oils. It forms crystals with a caramel-like odor, reminiscent of freshly baked cakes.

Although many routes are known for its synthesis, maltol is still isolated mainly from beechwood tar. It is used in aroma compositions with a caramel note and as a taste intensifier, for example, in fruit flavors (particularly in strawberry flavor compositions).

3-Pentyltetrahydro-2*H*-pyran-4-ol acetate [*18871-14-2*], $C_{12}H_{22}O_3$, M_r 214.30, *bp* (0.13 kPa) 102 – 103 °C, d_{25}^{25} 0.974 – 0.978, n_D^{20} 1.448 – 1.451, is a colorless to pale yellow liquid with a sweet-floral, fruity, slightly woody, jasmin-like odor. It is prepared by a Prins reaction of 1-octene with formaldehyde and acetic acid and is used in perfumes for various flower types, especially jasmin.

Trade Names. Jasmophyll (Haarmann & Reimer), Jasmopyran (Quest), Jasmal (IFF).

4,6,6,7,8,8-Hexamethyl-1,3,4,6,7,8-hexahydrocyclopenta[*g*]benzopyran [*1222-05-5*] (**35**), $C_{18}H_{26}O$, M_r 258.40, *bp* (1.1 kPa) 129 °C, d_4^{20} 1.0054, n_D^{20} 1.5342, is a viscous liquid with a musklike odor. It is one of the most frequently used synthetic, artificial musk fragrances. The starting material for its synthesis is 1,1,2,3,3-pentamethylindane, which is prepared by cycloaddition of *tert*-amylene to α-methylstyrene. The pentamethylindane is hydroxyalkylated with propylene oxide in a Friedel–Crafts reaction using aluminum chloride as a catalyst (analogous to the synthesis of 2-phenethyl alcohol from benzene and ethylene oxide, see page 51). Ring closure of the resulting 1,1,2,3,3-pentamethyl-5-(β-hydroxyisopropyl)indane to (**35**) is accomplished with paraformaldehyde and a lower aliphatic alcohol via the acetal [167] or with paraformaldehyde and a carboxylic acid anhydride via the acylate [168].

The commercial product is diluted with solvents (e.g., diethyl phthalate, isopropyl myristate, benzyl benzoate) to make it less viscous. It is alkali-stable and does not discolor in light. Therefore, it is a popular ingredient of perfume compositions for soaps, detergents, and cosmetics and is used in large amounts.
Trade Names. Galaxolide (IFF).

35

4,4*a*,5,9*b*-Tetrahydroindeno[1,2-*d*]-1,3-dioxane [*18096-62-3*], $C_{11}H_{12}O_2$, M_r 176.21, *bp* (1.3 kPa) 134 °C, *mp* 35 – 36 °C, $d_{15.5}^{15.5}$ 1.159, n_D^{20} 1.559, forms crystals with an indole-like odor. It is prepared by a Prins reaction from indene and formaldehyde in the presence of dilute sulfuric acid [169]. It is used in perfumes for soaps and detergents.

Trade Names. Indoflor (Haarmann & Reimer), Indolarom (IFF).

The 2,4-dimethyl homologue [*27606-09-3*] is prepared by using acetaldehyde instead of formaldehyde. Its odor is reminiscent of geranium and magnolia [171].

Trade Name. Magnolan (Haarmann & Reimer).

2,4,6-Trimethyl-4-phenyl-1,3-dioxane [*5182-36-5*], $C_{13}H_{18}O_2$, M_r 206.28, *bp* (300 Pa) 100 °C, d_4^{20} 1.159, n_D^{20} 1.504, is a colorless to pale yellow liquid. This cyclic acetal has a smell of grapefruit with herbal and fresh aspects.

2,4,6-Trimethyl-4-phenyl-1,3-dioxane can be produced by a Prins reaction of methylstyrene with acetaldehyde.

Trade Name. Vertacetal (DRAGOCO), Floropal (Haarmann & Reimer).

Isolongifolanone ethylene glycol acetal [*154171-77-4*], $C_{17}H_{28}O2$, M_r 264.41, *bp* (3 kPa) 142 – 143 °C, d_4^{20} 1.0510, n_D^{20}1.5051 is commercially available as a colorless liquid with strong woody odor with flowery-fresh effects and with a velvety moss/ambra accent. It has an extremely long lasting odor and acts as fixative. Isolongifolanone ethylene glycol acetal is frequently used in soaps, cosmetics, and perfumery compositions.

For the production of isolongifolanone acetal (**40**), longifolene (**36**), which is a main component of Indian turpentine oil, is first isomerized to isolongifolene (**37**). The epoxide (**38**), obtained by epoxidation of isolongifolene, is subsequently transformed to isolongifolanone (**39**), which is reacted with ethylene glycol to the cyclic isolongifolanone ethyleneglycolacetal (**40**) [170].

Trade Name. Ysamber-K (DRAGOCO).

5,5,7,9,9,13-Hexamethyl-4,6-dioxatetracyclo[6.5.1.^{1,10}0^{3,7}]tetradecane [*211299-54-6*], cedrene acetonide, $C_{18}H_{30}O_2$, M_r 278.44, *mp* 157 – 158 °C, is a fragrance compound with a powdery-woody, long-lasting amber note. Its industrial synthesis starts with the epoxidation of cedarwood oil fractions that contain sesquiterpene hydrocarbons, mainly α-cedrene. Acid-catalyzed ring opening and acetalization leads to cedrene acetonide [172].

The pure compound is crystalline and is frequently used in soaps, cosmetics and perfumery compositions as a fixative with high substantivity.

Trade Name. Ambrocenide 10 (DRAGOCO).

2.7.2. Lactones

Naturally occurring organoleptically important lactones are mainly saturated and unsaturated γ- and δ-lactones, and to a lesser extent macrocyclic lactones. The occurrence of these types of lactones reflects their ready formation from natural acyclic precursors.

The γ- and δ-lactones are the intramolecular esters of the corresponding hydroxy fatty acids. They contribute to the aroma of butter and various fruits. 3,4-Dimethyl-5-pentylidenedihydro-2(5*H*)-furanone [*774-64-1*] is an unsaturated γ-lactone with a distinct nutty flavor. 15-Pentadecanolide is responsible for the musklike odor of angelica root oil. Of the naturally occurring bicyclic lactones, phthalides are responsible for the odor of celery root oil, and coumarin for woodruff.

The macrocyclic esters hold a special position among the industrially produced lactone fra-

grance compounds. Like the well-known macrocyclic ketones (see Section 2.4), they have outstanding odor properties as musks. However, the lactones can be prepared more easily than the ketones, for example, by depolymerization of the corresponding linear polyesters. Since replacement of a methylene unit by oxygen affects the odor of these compounds very little, oxalactones with 15 – 17-membered rings are commercially produced in addition to 15-pentadecanolide. Several cyclic diesters prepared from long-chain α,ω-dicarboxylic acids and glycols are also valuable musk fragrances.

The γ-lactones described below can be prepared in good yield in a one-step process by radical addition of primary fatty alcohols to acrylic acid, using di-*tert*-butyl peroxide as a catalyst. A patent claims a high yield when the reaction is carried out in the presence of alkali phosphates or alkali sulfates [173].

γ-Lactones

γ-Octalactone [*104-50-7*], ($n = 3$), $C_8H_{14}O_2$, M_r 142.20, *bp* (1.3 kPa) 116 – 117 °C, d_4^{20} 0.977, n_D^{25} 1.4420, occurs as an aroma constituent in many processed and unprocessed foods. It is a pale yellow liquid with a fruity-coconut-like odor and is used both in aroma compositions and in heavy blossom perfumes.

γ-Nonalactone [*104-61-0*], ($n = 4$), "so-called aldehyde C_{18}" $C_9H_{16}O_2$, M_r 156.22, *bp* (1.7 kPa) 136 °C, d_4^{20} 0.9676, n_D^{20} 1.446, occurs in many foods and is a pale yellow liquid with a coconut-like aroma. It has numerous applications, similar to those of γ-octalactone, in aroma compositions and perfumery.
Trade Names. Abricolin (Haarmann & Reimer), Prunolide (Givaudan Roure).

γ-Decalactone [*706-14-9*], ($n = 5$), $C_{10}H_{18}O_2$, M_r 170.25, *bp* (2.3 kPa) 156 °C, d_4^{21} 0.952, $n_D^{19.5}$ 1.4508, is present in a wide variety of foods and is an almost colorless liquid with an intensely fruity odor, reminiscent of peaches. It is used in perfumery for heavy, fruity flower odors and in aroma compositions, particularly peach flavors.

γ-Undecalactone [*104-67-6*], ($n = 6$), "so-called aldehyde C_{14}" $C_{11}H_{20}O_2$, M_r 184.28, *bp* (2.0 kPa) 167 – 169 °C, d_4^{20} 0.944, n_D^{20} 1.4514, occurs in foods and is an almost colorless liquid with a peachlike odor. In addition to preparation by radical addition of 1-octanol to acrylic acid, γ-undecalactone is also prepared by intramolecular cyclization of 10-undecylenic acid with 70 – 80 % sulfuric acid with migration of the double bond.

γ-Undecalactone has many applications in perfume and aroma compositions, similar to those of γ-decalactone.
Trade Name. Pêche pure (Givaudan Roure).

δ-Decalactone [*705-86-2*], $C_{10}H_{18}O_2$, M_r 170.25, *bp* (3 Pa) 117 – 120 °C, $d_4^{27.5}$ 0.9540, n_D^{26} 1.4537, is a flavor constituent of many types of fruit, cheese, and other dairy products. It is a colorless, viscous liquid with a creamy-coconut, peachlike aroma.

δ-Decalactone can be prepared by peracid oxidation of 2-pentylcyclopentanone. It is used in perfumes and for cream and butter flavorings.

15-Pentadecanolide [*106-02-5*], ω-hydroxypentadecanoic acid lactone, $C_{15}H_{28}O_2$, M_r 240.39, *bp* (1.3 – 1.4 kPa) 169 °C, *mp* 37 – 38 °C, d_4^{40} 0.940, occurs in small quantities in, for example, angelica root oil. It forms colorless crystals with a delicate, musklike odor.

Production. The main industrial syntheses start from cyclododecatriene derivatives (→ Cyclododecatriene, Cyclooctadiene, and 4-Vinylcyclohexene). The 16-membered ring is formed either by expansion of the 12-membered ring or by depolymerization of polyesters of ω-hydroxypentadecanoic acid.

Preparation by Ring Expansion of Cyclododecanone. Radical addition of allyl alcohol to cyclododecanone, for example, with di-*tert*-butyl peroxide as a radical initiator, yields 2-(γ-hydroxypropyl)cyclododecanone (**41**). This is converted into 13-oxabicyclo-[10.4.0]hexadec-1(12)-ene (**42**)

by acid-catalyzed dehydration [174]. Addition of hydrogen peroxide, in the presence of sulfuric acid, gives 12-hydroperoxy-13-oxabicyclo[10.4.0]hexadecane (**43**). Cleavage of the peroxide by heating in xylene gives 15-pentadecanolide as well as a small amount of 15-pentadec-11(and 12)-enolide and 11 12-hydroxy-15-pentadecanolide [175].

Cyclododecanone **41**

42 **43**

15-Pentadecanolide

Preparation from Polyesters of 15-Hydroxypentadecanoic Acid.
In a Japanese process, the required ω-hydroxy acid is prepared from 1,12-dodecanediol in several steps. The diol is added to methyl acrylate in a radical reaction, using di-*tert*-butyl peroxide as a catalyst. The free hydroxyl group in the resulting ω-hydroxy-γ-pentadecalactone is acetylated with acetic anhydride, and the resulting ω-acetoxy-γ-pentadecalactone is converted into 15-hydroxypentadecanoic acid by hydrogenolysis and hydrolysis [176] (see upper one of following figures).
Another route to 15-hydroxypentadecanoic acid starts from 13-oxabicyclo[10.4.0]hexadec-(1,12)-ene (**42**), see (1). Nitrosation to 12-oximino-15-pentadecanolide, followed by a Wolff–Kishner reduction yields 15-hydroxypentadecanoic acid [177]. The reaction can be carried out without isolation of the intermediate oxime.

15-Hydroxypentadecanoic acid

42

The polyester of 15-hydroxypentadecanoic acid is prepared by customary methods and is cleaved under high vacuum in the presence of transesterification catalysts.

Uses. 15-Pentadecanolide is a highly valuable fragrance material that is used in fairly large amounts in fine fragrances as a fixative with a delicate musk odor.
Trade Names. Cyclopentadecanolid (Haarmann & Reimer), Exaltolid (Firmenich), Pentalide (Soda Aromatic).

Oxacyclohexadec-12/13-en-2-one, (*E/Z*) [*34902-57-3*], $C_{15}H_{26}O_2$, M_r 238, *bp* (40 Pa) 88 – 93 °C , d_{20}^{20} 0.961 – 0.971, possesses a musklike, ambrette, and animalic odor.

Production (see production of 15-pentadecanolide page 77). Cleavage of 12-hydroperoxy-13-oxabicyclo[10.4.0]-hexadecane (**43**) in the presence of $Cu(OAc)_2$ and $Fe(SO_4)_2$ gives 43 % of *trans*-pentadec-11-enolide, 26 % *trans*-pentadec-12-enolide, 18 % *cis*-pentadec-11-enolide, 5 % *cis*-pentadec-12-enolide, and 5 % pentadecanolide [178].

Another synthesis uses a pyrolysis of an acetoxy derivative of the lactone [179].

Uses. 15-Pentadec-11/12-enolide is a very powerful musk and combines the strength and tenacity of the aromatic musks with the pleasantness and elegance of the macrocyclic musks.
Trade Names. Habanolide (Firmenich), Globalide (Haarmann & Reimer).

12-Oxa-16-hexadecanolide [*6707-60-4*], 16-hydroxy-12-oxahexadecanoic acid lactone, $C_{15}H_{28}O_3$, M_r 256.38, does not occur in nature. Its odor is comparable to that of 15-pentadecanolide, but less intense. It is prepared by reacting methyl ω-bromoundecanoate with the monosodium salt of 1,4-butanediol. The resulting methyl 16-hydroxy-12-oxapalmitate is condensed to the corresponding polyester, which is subsequently depolymerized.

12-Oxa-16-hexadecanolide

12-Oxa-16-hexadecanolide as well as the stronger smelling 11-oxa isomer [*3391-83-1*], which is obtained in the same way from the corresponding hydroxyoxa acid, are used as substitutes for 15-pentadecanolide in fine fragrances.

11-Oxa-16-hexadecanolide

Trade Names. 12-Oxa-16-hexadecanolide = Cervolide (Quest), 11-Oxa-16-hexadecanolide = Musk R 1 (Quest).

α,ω-Dodecanedioic acid ethylene ester [*54982-83-1*], (**44**, $n = 10$), $C_{14}H_{24}O_4$, M_r 256.34, *mp* 18 °C, *bp* (2.7 kPa) 139 – 141 °C, d_4^{60} 1.0303, n_D^{40} 1.4588, is a synthetic musk that is prepared by thermal depolymerization of the polyester obtained from 1,12-dodecanedioic acid and ethylene glycol in the presence of a catalyst (e.g., stannous salts of aliphatic monocarboxylic acids) [180].

44

The compound is used in perfumery as a musk fragrance, but is not as long-lasting as the following homologous compound, ethylene brassylate.
Trade Name. Arova 16 (Degussa).

α,ω-Tridecanedioic acid ethylene ester [*105-95-3*], ethylene brassylate (**44** ,$n = 11$), $C_{15}H_{26}O_4$, M_r 270.37, *bp* (1.3 kPa) 140 °C, d_4^{60} 1.0180, n_D^{20} 1.4702, is an artificial fragrance compound, with a sweetish, slightly fatty, musk odor. Like α,ω-dodecanedioic acid ethylene ester, the ester is obtained by depolymerization of the corresponding polyester. Brassylic acid (α,ω-tridecanedioic acid) is prepared by ozonolysis of erucic acid [181]:

Ethylene brassylate is used in large amounts in perfumery as a fixative and for rounding off sweet-flowery odor notes.
Trade Name. Musk T (Takasago), Ethylene Brassylate (Degussa).

Coumarin [*91-64-5*], 2*H*-1-benzopyran-2-one, $C_9H_6O_2$, M_r 146.15, *bp* (1.33 kPa) 153.9 °C, *mp* 70.6 °C, d_4^{20} 0.935, occurs widely in nature and determines, for example, the odor of woodruff. It forms white crystals with a hay-like, spicy odor. When treated with dilute alkali, coumarin is hydrolyzed to the corresponding coumarinic acid salt (*cis*-2-hydroxycinnamic

acid). Heating with concentrated alkali or with sodium ethanolate in ethanol results in the formation of *o*-coumaric acid salts (*trans*-2-hydroxycinnamic acid). 3,4-Dihydrocoumarin is obtained by catalytic hydrogenation, for example, with Raney nickel as a catalyst; octahydrocoumarin is obtained if hydrogenation is carried out at high temperature (200 – 250 °C).

Production. Coumarin is currently produced by Perkin and Raschig syntheses.

Synthesis from Salicylaldehyde by the Perkin Reaction.
In the presence of sodium acetate, salicylaldehyde reacts with acetic anhydride to produce coumarin and acetic acid. The reaction is carried out in the liquid phase at elevated temperature.

Coumarin

In a special process, the sodium acetate catalyst is retained in the reactor by a built-in filter and is reused [182].
Synthesis from o-Cresol by the Raschig Process.

Coumarin

The hydroxyl group of *o*-cresol is protected by a carbonate or phosphate group, and the ester can be converted into the corresponding benzal chloride derivative by chlorination of the methyl group. Reaction of this intermediate with acetic anhydride yields *O*-acetylsalicylaldehyde and acetyl chloride. Ring closure of the aldehyde with acetic anhydride gives coumarin.
Since the odor of coumarin is relatively weak, strong-smelling byproducts (e.g., vinylphenol) must be removed. Many purification methods have been reported and patented.

Uses. Coumarin is one of the most widely used fragrance compounds. It is used in fine fragrances as well as in soap perfumes for spicy green notes. It is also used in galvanization as a brightener.

Dihydrocoumarin [*119-84-6*], 3,4-dihydro-2*H*-benzopyran-2-one, $C_9H_8O_2$, M_r 148.16, *bp* (2.3 kPa) 145 °C, *mp* 24 °C, n_D^{25} 1.5528, occurs in a few essential oils and forms colorless crystals with a sweet-herbal odor. Dihydrocoumarin is prepared by hydrogenation of coumarin, for example, in the presence of a Raney nickel catalyst. Another process employs the vapor-phase dehydrogenation of hexahydrocoumarin in the presence of Pd or Pt–Al_2O_3 catalysts [183]. Hexahydrocoumarin is prepared by cyanoethylation of cyclohexanone and hydrolysis of the nitrile group, followed by ring closure to the lactone [184].

Dihydrocoumarin is used in woodruff-type flavor compositions. (Limiting IFRA recommendation)

2.7.3. Glycidates

A number of glycidates are important intermediates in the synthesis of fragrance compounds. They are prepared either by epoxidation of the corresponding acrylates or by condensation of aldehydes or ketones with α-chloro substituted fatty acid esters (Darzens reaction).

Ethyl 3-phenylglycidate [*121-39-1*], "so-called special aldehyde C_{16}", $C_{11}H_{12}O_3$, M_r 192.21, *bp* (40 Pa) 104 °C, d_4^{20} 1.1023, n_D^{30} 1.5095, is a colorless liquid with a strawberry-like odor; it is not known to occur in nature.

It is prepared by treating ethyl cinnamate with peracetic acid [185] or by condensation of benzaldehyde with ethyl chloroacetate (in the above Darzens reaction, R = H). The glycidate is used as a long-lasting fragrance compound for creating harmonic, fruity notes in household and fine fragrances.

Ethyl 3-methyl-3-phenylglycidate [*77-83-8*], "so-called aldehyde C_{16}", $C_{12}H_{14}O_3$, M_r 206.24, *bp* (2.4 kPa) 153–155 °C, d_{25}^{25} 1.506–1.513, occurs in two optically active pairs of *cis*- and *trans*-isomers; each isomer has a characteristic odor [186]. The commercial product is a racemic mixture of all four isomers and has a strong, sweetish, strawberry odor. The *cis* : *trans* ratio obtained in the Darzens condensation of acetophenone ($R = CH_3$) and ethyl chloroacetate depends on the base used in the reaction.

The glycidate is used in household perfumery for fruity notes.
Trade Name. Fraise pure (Givaudan Roure).

2.7.4. Miscellaneous Compounds

2-Furylmethanethiol [*98-02-2*], furfuryl mercaptan, C_5H_6OS, M_r 114.16, *bp* (101.3 kPa) 160 °C, d_4^{20} 1.1319, n_D^{20} 1.5329, is an important constituent of the aroma of roasted coffee. It is a liquid with an unpleasant odor, which becomes like coffee when diluted. Furfuryl mercaptan is prepared from furfuryl alcohol, thiourea, and hydrogen chloride. The resulting *S*-furfurylisothiouronium chloride is cleaved with sodium hydroxide to give furfuryl mercaptan.

The thiol is used in coffee aromas.

2.8. N- and N, S-Heterocycles

Many nitrogen- and sulfur-containing heterocycles have been identified in the aroma fractions of foods [187]. In roasted products (e.g., coffee) and heat-treated foods (e.g., baked bread or fried meat), these heterocycles are formed from reducing sugars and simple or sulfur-containing amino acids by means of Maillard reactions [188, 189]. Their odor threshold values are often extremely low and even minute amounts may significantly contribute to the aroma quality of many products [190, 191]. Therefore, N- and N, S-heterocyclic fragrance and flavor substances are produced in far smaller quantities than most of the products previously described.

Pyrroles, indoles, pyridines, quinolines, and pyrazines are examples of N-heterocycles that are produced as fragrance and flavor compounds. Thiazoles and dithiazines are examples of nitrogen- and sulfur-containing heterocycles. These heterocyclic compounds are mainly used in aroma compositions, exceptions are indoles and quinolines, which are important fragrance substances.

Representatives of the above-mentioned classes are as follows:

2-Acetylpyrrole [*1072-83-9*], roast odor

2-Acetyl-3,4-dihydro-5*H*-pyrrole [*85213-22-5*], characteristic odor of white bread crust

Indole [*120-72-9*], fecal odor, floral in high dissolution

3-Methylindole, skatole [*83-34-1*], indole-like odor

2-Acetylpyridine [*1122-62-9*], roast odor

6-Methylquinoline [*91-62-3*], blossom odor, sweet-animalic upon dissolution

6-Isobutylquinoline [*68141-26-4*], mossy-earthy odor

2-Acetylpyrazine [*22047-25-2*], popcorn-like odor

2-Methoxy-3-isopropylpyrazine [*25773-40-4*], green pea odor

2-Methoxy-3-isobutylpyrazine [*24683-00-9*], green-pepper odor

2,3-Dimethylpyrazine [*5910-89-4*], and its 2,5- [*123-32-0*] and 2,6- [*108-50-9*] isomers, roast odor, reminiscent of nuts

Trimethylpyrazine [*14667-55-1*], roast odor, reminiscent of coffee and cocoa

Mixture of 3-ethyl-2,5-dimethylpyrazine [*13360-65-1*] and 2-ethyl-3,5-dimethylpyrazine [*13925-07-0*], roast odor, reminiscent of nuts

2,5-Dimethylthiazole [*4175-66-0*], meat-like odor

2-Isobutylthiazole [*18640-74-9*], tomato odor

and

R = Methyl, isopropyl, isobutyl, 2-methylbutyl

Alkyldimethyl-1,3,5-dithiazines, roast odor

3. Natural Raw Materials in the Flavor and Fragrance Industry

3.1. Introduction

Although synthetic flavor and fragrance materials are produced on an industrial scale, naturally occurring raw materials continue to be essential, important ingredients in the manufacture of flavor and fragrance compositions for several reasons. First, the composition and organoleptic nature of natural products are often too complex to be reproduced by a combination of synthetic fragrance substances. Second, the characteristic flavor and fragrance substances of a particular product often cannot be synthesized at a competitive price. Third, the use of natural materials in the production of certain flavor compositions is compulsory. Demand for perfumes based on natural materials has increased.

Raw materials for the flavor and fragrance industry are obtained from more than 250 different plant species, but only a handful of products originate from animals.

Raw materials are isolated from various parts of plants, e.g., blossoms, buds, fruit, peel, seeds, leaves, bark, wood, roots, or from resinous exudates. Different parts of the same plant may yield products with different compositions. For instance, steam distillation of the bark of the cinnamon tree gives cinnamon bark oil, which contains mainly cinnamaldehyde, whereas cinnamon leaf oil obtained from the leaves of the tree contains eugenol as its major constituent.

The quality of natural products depends considerably on their geographic origin, even if they are isolated from the same plant species. This may be partly due to variations in cultivation conditions, such as soil structure and climate, but also results from the fact that different varieties of the same plant species are cultivated in different areas. Thus, more than 500 natural raw materials are available for the creation of perfumes and flavors.

The flavor and fragrance industry has expanded so much that the plants required to supply the raw materials are now grown on a very large scale. Examples are the peppermint and spearmint plantations in the United States and the lavandin plantations in southern France.

The economic importance of the cultivation of aromatic plants has led to the systematic breeding of new varieties. New species are obtained either by alternation of generations or by vegetative means in an attempt to improve yield, oil quality, and resistance to disease and insects.

The production of some essential oils has decreased to low levels or even been discontinued due to competition from synthetic products. Nevertheless, the worldwide production of flavor and fragrance materials of natural origin has increased recently due to breeding successes, but their total market share has decreased. Annual worldwide sales currently amount to $\$600 \times 10^6$ [192].

Raw materials derived from intensive agricultural cultivation are usually relatively inexpensive. However, the prices of some natural materials may exceed \$1000 per kilogram because cultivation and harvesting of these plants are tedious and product yields are very low. Examples of extremely valuable ingredients of fragrance and flavor creations include rose oil, jasmine absolute, tuberose absolute, orris root oil, ambrette seed oil, angelica root oil, and orange flower oil.

3.2. Isolation of Natural Fragrance and Flavor Concentrates

Three main methods are used to concentrate plant flavor and fragrance substances:

1) distillation
2) mechanical separation ("pressing")
3) solvent extraction

The qualitative and quantitative composition and, thus, the organoleptic properties of the product depend on the isolation procedure. For example, an extract contains large amounts of nonvolatile components that are not found in essential oils obtained by distillation. Since these components markedly influence odor development (complexing and fixing), the two products may have completely different organoleptic properties, even though the compositions of their odorous volatile constituents are comparable.

In addition, the distillation of essential oils at elevated temperature results in the transformation of thermolabile substances, and some typical components are only released from their precursors in the plants under distillation conditions.

Solvent extraction is generally applied in the separation of heat-labile plant materials or if an essential oil can be obtained only in very low yield (e.g., from blossoms). It is also used if the nonvolatile components are desired for their fixative properties (e.g., in the preparation of resinoids from exudates).

3.2.1. Essential Oils

Production. Essential oils are obtained from plant materials by distillation with water or steam. After condensation of the vapor phase, the oil separates from the aqueous phase and is removed. The yield of essential oil, based on the starting plant material, generally ranges from a few tenths of 1 % to a few percent. The apparatus used in the production of natural fragrance concentrates is described in [193].

Essential oils consist of volatile, lipophilic substances that are mainly hydrocarbons or monofunctional compounds derived from the metabolism of mono- and sesquiterpenes, phenylpropanoids, amino acids (lower mass aliphatic compounds), and fatty acids (long-chain aliphatic compounds). Unlike fatty oils, essential oils do not leave a grease stain when dabbed on filter paper.

Essential oils are to be distinguished from the so-called *distillates,* which are ethanol-containing products that are obtained from plant materials by distillation with ethanol or with ethanol–water mixtures. *Essence oils* are defined as essential oils that separate from the aqueous phase in the distillation receiver during the distillative concentration of fruit juices (usually citrus juices). *Citrus peel oils* are a special type of essential oil. They are isolated by pressing the peel to release the volatile substances stored in the pericarp in small oil glands. The resulting products are termed essential oils because they consist largely of highly volatile terpene hydrocarbons. However, they also contain small amounts of nonvolatile compounds, such as dyes, waxes, and furocoumarins.

Uses. Most essential oils are used directly as starting materials in the production of flavor and fragrance compositions. However, some essential oils are fractionated or concentrated by distillation, partitioning, or adsorption. Substances that are important for the desired characteristic odor and taste are thus concentrated, and other components, which possess either an unpleasant or very faint odor or are unsuitable for the application in question, are removed.

Individual compounds can be isolated from essential oils containing one or only a few major components by distillation or crystallization. Examples are eugenol from clove oil, menthol from cornmint oil, citronellal from *Eucalyptus citriodora* oil and citral from *Litsea cubeba* oil. These compounds are used as such or serve as starting materials for the synthesis of derivatives, which are also used as flavor and fragrance substances. However, the importance of some of these oils has decreased substantially because of the development of selective synthetic processes for their components.

Although essential oils or their fractions are mixtures of many substances, these oils are occasionally converted as a whole into derivatives. Examples of such derivatives are vetiveryl acetate from vetiver oil, guaiyl acetate from guaiac wood oil, and acetyl cedrene from cedarwood terpenes. These products are also employed as fragrance substances.

3.2.2. Extracts

Extracts of fragrance and flavor substances obtained from plants are termed pomades, concretes, absolutes, resinoids, or tinctures according to their method of preparation.

Pomades consist of fats that contain fragrance substances and are produced by the hot or cold enfleurage of flowers. *Hot enfleurage* is the oldest known procedure for preserving plant fragrance compounds. In this method, flowers (or other parts of a plant) are directly immersed in liquid or molten wax.

In *cold enfleurage,* the volatile components released by flowers into their sourroundings are absorbed with fats over a longer period of time. This industrial procedure was developed in southern France in the 19th century for the production of high-grade flower concentrates. It involves the application of fresh flowers to a fat layer, consisting of a mixture of specially refined lard and beef tallow, which is spread on a glass

plate in a closed container. This method, however, has been almost totally replaced by the less tedious technique of solvent extraction.

Concretes are prepared by extracting fresh plant material with nonpolar solvents (e.g., benzene, toluene, hexane, petroleum ether). On evaporation, the resulting residue contains not only volatile fragrance materials, but also a large proportion of nonvolatile substances including waxy compounds. For this reason, concretes (like pomades) are not completely soluble in alcohol and, thus, find limited use as perfume ingredients. However, they can be employed in the scenting of soaps.

Concretes, which are actually intermediate products (see below), are prepared mainly from flowers (rose, jasmine, tuberose, jonquil, ylang-ylang, mimosa, boronia, etc.), but also from other plant materials (lavender, lavandin, geranium, clary sage, violet leaves, oak moss, etc.). A yield of ca. 0.3 % based on the starting flower material, is obtained in the production of jasmine concrete.

Absolutes are prepared by taking up concretes in ethanol. Compounds that precipitate on cooling are then removed by filtration. After evaporation of the ethanol, a wax-free residue called an absolute is left behind. Absolutes are completely soluble in ethanol and, therefore, can be freely used as perfume ingredients. They are usually formed in a yield of ca. 50 %, based on the concrete as starting material.

In rare cases, absolutes can be obtained directly by extracting the plant material with alcohol (e.g., tonka absolute).

Resinoids are prepared by extracting plant exudates (balsams, oleo gum resins, natural oleo resins, and resinous products) with solvents such as methanol, ethanol, or toluene. Yields range from 50 to 95 %. The products are usually highly viscous and are sometimes diluted (e.g., with phthalates or benzyl benzoate) to improve their flow and processing properties.

Resinoids mainly consist of nonvolatile, resinous compounds and are primarily used for their excellent fixative properties.

The resinoids described above should be distinguished from prepared *oleoresins* (e.g., pepper, ginger, and vanilla oleoresins), which are concentrates prepared from spices by solvent extraction. The solvent that is used depends on the spice; currently, these products are often obtained by extraction with supercritical carbon dioxide. Pepper and ginger oleoresins contain not only volatile aroma compounds, but also substances responsible for pungency.

Tinctures are alcoholic solutions that are prepared by treating natural raw materials with ethanol or ethanol–water mixtures. They can also be obtained by dissolving other extracts in these solvents. Tinctures are sometimes called *infusions.*

3.3. Survey of Natural Raw Materials

The following survey of the most important, well-known raw materials used in the flavor and fragrance industry is by no means complete; the materials are listed in alphabetical order. Physical standards for essential oils are described as specified by the ISO or the Essential Oil Association of the United States (EOA). The physical standards cited according to ISO are taken from the most recent draft, because many standards are already very old but under discussion. The ISO standard number remains the same; so the reader can also check for the older data. EOA specifications were only cited in those cases where no ISO specifications are available. These become more and more the most widely distributed standards. Gas chromatograms are widely used for analysis and quality control, but have not been included due to lack of space. Further details are given in the literature, e.g., [194], and in ISO specifications, which now include gas chromatograms.

The entire components of the individual products have not been listed for the same reason; further information is available in the literature, e.g., [187, 195]. Physical data for extracts or concentrates consisting largely of nonvolatile material are not given because the composition of these products varies widely according to the isolation and manufacturing procedure used.

The botanical names of plants are cited in accordance with the International Code of Botanical Nomenclature (ICBN) as described, for example, in [196].

Allium oils are obtained from garlic and onion (Liliaceae). Their quality is assessed on the basis of their odor and aroma rather than their physical and chemical properties. The EOA specifications given below are, therefore, of limited value only.

1) *Garlic oil* is obtained by steam distillation of crushed bulbs of the common garlic, *Allium sativum* L.; it is a clear, reddish-orange liquid, with a strong, pungent, characteristic garlic odor.
   d_{25}^{25} 1.040 – 1.090, n_D^{20} 1.5590 – 1.5790 [197]. Diallyl disulfide [*2179-57-9*] is an essential odor component of garlic oil:
   $CH_2{=}CHCH_2SSCH_2CH{=}CH_2$
2) *Onion oil* is obtained by steam distillation of the crushed bulbs of the common onion, *Allium cepa* L. It is an amber-yellow to amber liquid with a strongly pungent, lasting, characteristic onion odor.
   d_{25}^{25} 1.050 – 1.135; n_D^{20} 1.5495 – 1.5695 [198].
   Aliphatic sulfur compounds, in particular disulfides such as methyl propyl disulfide, dipropyl disulfide, and especially *cis*- and *trans*-propenyl propyl disulfide are mainly responsible for the typical odor of onion oil. Garlic and onion oil are used in seasoning mixtures for the food industry.

Allspice oil, see Pimento Oils, page 113.

Ambergris (ambra), see Animal Secretions, page 87.

Ambrette seed oil is obtained by steam distillation of the dried, crushed seeds of *Abelmoschus moschatus* Medik. (*Hibiscus abelmoschus* L., Malvaceae), a flowering shrub growing in tropical areas. Due to its content of long-chain fatty acids, the crude product is a waxy mass and, therefore, also called "Ambrette beurre." Removal of the fatty acids with alkali gives a clear yellow to amber-yellow liquid with the strong, musky odor of ambrettolide.

d_{25}^{25} 0.898 – 0.920; n_D^{20} 1.4680 – 1.4850; $[\alpha]_D$ $-2°30'$ to $+3'$; acid value: max. 3; saponification value: 140 – 200 [199].

The constituents responsible for the musk odor of the oil are ambrettolide, (*Z*)-7-hexadecen-16-olide [*123-69-3*] and (*Z*)-5-tetradecen-14-olide [*63958-52-1*]:

5-Tetradecen-14-olide

Ambrettolide

Other components are acyclic aliphatic esters and terpenes, such as farnesol and farnesyl acetate. Ambrette seed oil is one of the most expensive essential oils and, thus, is used mainly in fine fragrances.

Amyris oil is obtained by steam distillation of the wood from the tree *Amyris balsamifera* L. (Rutaceae), which grows in the Caribbean area and around the Gulf of Mexico. Annual production worldwide is ca. 40 t. It is a pale yellow to amber-yellow, slightly viscous liquid with a mild wood odor.

d_{20}^{20} 0.946 – 0.978; n_D^{20} 1.505 – 1.510; $[\alpha]_D^{20}$ + 10 ° to + 60 °; solubility: 1 vol in 1 vol of 90 % ethanol at 20 °C; solutions sometimes become opalescent on dilution; acid value: max. 3.0; ester value (after acetylation): 180 – 198 [200].

The oil is sometimes incorrectly called West Indian sandalwood oil. However, its composition and odor are different from those of the oils obtained from sandalwood species. The major components of amyris oil are sesquiterpenoids such as valerianol [*20489-45-6*], elemol [*639-99-6*], β-eudesmol [*473-15-4*], and *epi*-γ-eudesmol [*15051-81-7*] [201].

epi-γ-Eudesmol

Amyris oil is used in perfume compositions, mainly as a fixative.

Angelica oil is prepared from *Angelica* roots or seeds.

1) *Angelica root oil* is obtained by steam distillation of the dried roots of *Angelica archangelica* L. Apiaceae [*Archangelica officinalis* (Moench) Hoffm.], a plant occurring predominantly in Europe. The oil is a pale yellow to deep amber-yellow liquid with a green, herbaceous, peppery, musk-like odor and a bitter-sweet taste.

d_{25}^{25} 0.850 – 0.880, occasionally up to 0.930 for oils from stored roots; n_D^{20} 1.4735 – 1.4870; $[\alpha]_D$ 0° to +46°; acid value: max. 7; ester value: 10 – 65; solubility: 1 vol in at least 1 vol of 90 % ethanol, often with turbidity [202]. (Limiting IFRA recommendation)

2) *Angelica seed oil* is similarly obtained from fresh seeds of the plant. It is a light yellow liquid with an odor that is sweeter and more delicate than that of the root oil.
d_{25}^{25} 0.853 – 0.876; n_D^{20} 1.4800 – 1.4880; $[\alpha]_D$ +4° to +16°; acid value: max. 3; ester value: 14 – 32; solubility: 1 vol in at least 4 vol 90 % ethanol, often with considerable turbidity [203].
Angelica root oil contains ca. 90 % terpenoids and sesquiterpenoids. α-Pinene, 3-carene, limonene, and β-phellandrene are the major components (together ca. 60 %). In addition, the oil contains a large number of oxygen-containing compounds, of which the macrolides 15-pentadecanolide and 13-tridecanolide are essential odor components. The two angelica oils are used mainly in the alcoholic beverage industry.

Animal secretions are of minor commercial importance because some of the animal species from which they are obtained are virtually extinct, and the killing quota for others has been sharply reduced. Few odoriferous secretions of mammals have actually been shown to possess pheromone-like properties linked with reproduction. However, the odor of animal secretions is known to be important for communication and behavior of a particular species. Most of the products described below contain strong-smelling compounds with relatively high molecular masses. Therefore, they are used as longlasting fragrance complexes. Most of their odoriferous constituents are now produced synthetically and are used for the same purposes.

1) *Ambergris* (*ambra*) is a secretion of the sperm whale *Physeter catodon* (*P. macrocephalus* L.), that possibly results from a pathological condition. Ambergris has a lower density than water and washes ashore along the ocean coasts. The major quantity is obtained from killed animals, but only a low percentage contain ambergris in their intestines.

Fresh ambergris is almost black, but it turns light gray and develops a pleasant odor when exposed to light and seawater over a period of time. The major components of ambergris are epicoprosterol (up to 85 %) and the odorless triterpene alcohol, ambrein [*473-03-0*].

Ambrein

Ambrein is the likely precursor of a number of strongly odoriferous mono-, bi-, and tricyclic compounds that are formed by autoxidation or photooxidation [204]. Examples are as follows:

γ-Dihydroionone [*13720-12-2*] (odor: tobacco)

2-Methylene-4-(2,2-dimethyl-6-methylenecyclohexyl)butanal [*72892-63-8*] (odor: seawater)

α-Ambrinol [*41199-13-3*] (odor: moldy, animal, fecal)

3a,6,6,9a-Tetramethyldodecahydronaphtho[2,1-b]furan [*6790-58-5*] (odor: ambergris)

Together, these compounds largely represent the odor of ambergris. Ambergris is applied as a 3 % tincture in 90 % ethanol, which is matured by standing over a period of time

with occasional shaking. It is used in fine fragrances.

2) *Beeswax absolute* is obtained by alcohol extraction of beeswax. The yield is generally less than 1 %. The yellowish-brown viscous product has a mild, honey-like odor and high tenacity; it is used almost exclusively in fine fragrances.

3) *Castoreum* is an unpleasantly sharp-smelling, oily substance secreted by special glands of beavers, *Castor fiber* L. (Castoridae), living in Canada, Alaska, and Siberia. Both sexes secrete the substance, which accumulates in an abdominal pouch, also called castoreum. Dilute castoreum (e.g., as a tincture in ethanol) smells pleasantly of birch tar and musk and is slightly fruity.
   Castoreum is a byproduct of the fur industry. The beaver pouches are dried in the air or over a wood fire; the color of their contents then changes from yellow to dark brown, and the consistency from a butter-like to resinous character.
   In addition to alcoholic tinctures, castoreum is available in the form of resinoids, which are prepared by extracting dried, comminuted pouches with acetone, benzene, or ethanol; yields are 30 – 50 %, 20 – 25 %, and 45 – 80 %, respectively. The resinoids have the following specifications [205]

Acid value	15 – 30	30 – 35	15 – 30
Ester value	145 – 200	145 – 200	145 – 200
Carbonyl value	55 – 70	40 – 60	10 – 20

   The intense, for the Siberian beaver leathery, odor of castoreum is caused largely by phenolic compounds (e.g., 4-alkylphenols and catechol derivatives), which beavers take in with their food and excrete into their abdominal pouch. Castoreum is used mainly in fine fragrances for its characteristic, long-lasting odor, particularly for delicate leather nuances.

4) *Civet* is a glandular secretion produced by both sexes of the civet cat (Viverridae). Two species are known: *Civetticitis civetta* that inhabits Ethiopia, and *Viverra zibetha* that is found in India, Malaya, Indochina, and Indonesia.
   The animals are kept in cages, and the fresh secretion is taken from the pouches at regular (about one-week) intervals. Civet is almost liquid with a light yellow color. It darkens when exposed to light and takes on a consistency like salve. In dilutions (e.g., as an alcoholic tincture), civet has a pleasant, sweetish odor. A resinoid prepared by extraction with acetone is a dark brown-red mass; *mp* 20 – 25 °C; acid value: 100 – 140; ester value: 20 – 40; carbonyl value: 15 – 25 [206]. Civetone (for formula, see Section 2.4) is the main odoriferous constituent of civet (2.5 – 3.4 %). Civet contains other macrocyclic ketones such as cyclohexa- and cycloheptadecanone and 6-*cis*-cycloheptadecenone. Traces of indole and skatole contribute to the animal note.
   Civet has a distinctly different odor from musk and was formerly a versatile ingredient of fine fragrances.

5) *Musk* is secreted exclusively by the male animals of *Moschus moschiferus,* a wild deer living in the mountains of Nepal, Tibet, and Mongolia. The light yellow secretion with a salve consistency accumulates in an abdominal pouch and probably serves to attract females. When the pouch is dried, the secretion solidifies to form a brittle, brown mass with a characteristic odor. Since several *Moschus* species occur, large variations exist in the quality and specifications of musk. Hunting of the animals has been prohibited; therefore, only small quantities of musk are available at extremely high prices.
   (−)-Muscone and related macrocyclic ketones are responsible for the odor of musk [207]. Like other animal secretions, musk is preferentially used as an alcoholic tincture in fine fragrances.

Anise oil is obtained by steam distillation of the fruits of *Pimpinella anisum* L. (Apiaceae). It is a colorless to pale yellow liquid or crystalline mass with a powerful, sweet odor, characteristic of anethole.

d_{20}^{20} 0.980 – 0.990; n_D^{20} 1.552 – 1.561; $[\alpha]_D^{20}$ − 2 ° to + 2 °; solubility: 1 vol in 3 vol of 90 % ethanol at 20 °C; *fp* 15 – 19.5 °C [208].

The main component of anise oil is *trans*-anethole, which may be present at a concentration up to 94 % and which determines the melting point of the oil.

The oil was formerly produced in many countries, mainly in eastern Europe, but has now been

replaced to a large extent by the less expensive star anise oil (see page 117), which also contains a high percentage of anethole. Annual worldwide production of both oils is ca. 500 t.

Anise oil is used for flavoring foods, beverages, and oral hygiene products.

Armoise oil is obtained by steam distillation of the herb *Artemisia herba-alba* Asso (Asteraceae) that grows in Morocco. It is a light yellow to yellow liquid with a light herbaceous odor characteristic of thujone.

d_{25}^{25} 0.917 – 0.935; n_D^{20} 1.4600 – 1.4720; $[\alpha]_D^{20}$ – 25 ° to – 8 °.

The major components of armoise oil (Marrakesh-type) are the ketones camphor (40 %) and α- and β-thujone (35 % and 5 % respectively). Since *Artemisia herba-alba* exists as various chemotypes, the composition of the oil may vary widely. For example, each of the above-mentioned ketones may occur in a concentration over 50 % or less than 10 %.

Armoise oil is used in fairly large amounts in fine fragrances (e.g., for chypre notes).

Basil oil is available in several types that differ in their major components; the two most important are described.

1) *Réunion basil oil* is obtained by steam distillation of the flowering tops or whole plants of *Ocimum basilicum* L. (Lamiaceae). This oil is produced mainly in Réunion, the Comores, Madagascar, and the Seychelles. It is a pale yellow to amber-yellow liquid with a fresh, green, spicy odor characteristic of estragole. d_{20}^{20} 0.948 – 0.970; n_D^{20} 1.5100 – 1.5200; $[\alpha]_D^{20}$ – 1 ° to + 2 °; solubility: 1 vol in 7 vol of 80 % ethanol [209].
   The oil typically has a high content of methylchavicol (min. 75 %, max. 85 %).

R = H_3C, methylchavicol (estragole) [*140-67-0*]
R = H, chavicol [*501-92-8*]

   Annual production (ca. 200 to 300 t) is used predominantly for seasoning foods.
2) *European basil oil* is produced mainly in France, Italy, the Balkan countries, Egypt, and South Africa. The major components of this oil are linalool (35 – 50 %) and methylchavicol (15 – 25 %). It is used for food flavoring and in perfumery.

Bay oil is obtained by steam distillation of the leaves of *Pimenta racemosa* (Mill.) J. W. Moore (Myrtaceae). It is a dark brown liquid with a strong, spicy, clovelike odor.

d_{20}^{20} 0.943 – 0.984; n_D^{20} 1.505 – 1.517; $[\alpha]_D^{20}$ close to 0 °; phenols content: min. 50 % [210].

Evergreen bay trees or bay-rum trees, which are up to 12 m high, grow wild and are also cultivated in northern South America and in the West Indies. The main cultivation area is the island of Dominica.

The major components of the oil are myrcene, eugenol, and chavicol. The phenol content is determined largely by the latter two compounds.

Total production of bay oil is ca. 50 t/a. It has antiseptic properties because of its high phenol content and is, therefore, used for perfuming after-shave lotions.

Benzoe Siam resinoid is obtained by solvent extraction of the resin from *Styrax tonkinensis* (Pierre) Craib ex Hartwich trees (Styracaceae). The wild growing *Styrax* tree is widespread in Thailand, Laos, Cambodia, and Vietnam.

Benzoe Siam resinoid is a reddish to light brown, viscous liquid with a long-lasting, chocolate-like, sweet, balsamic odor. It is used in perfumery for balsamic nuances and as a fixative. (IFRA recommendation)

Benzoe Sumatra resinoid is obtained by solvent extraction of the resin from *Styrax benzoin* Dryand, a tree growing predominantly on the island of Sumatra. Benzoe Sumatra resinoid is a dark brown viscous liquid with a warm, powdery, sweet-balsamic odor. Its main volatile, odor-determining components are derivatives of benzoic and cinnamic acids and vanillin [211].

Benzoe Sumatra resinoid is used in perfumery, mainly as a fixative with a warm, balsamic note. (IFRA recommendation)

Bergamot oil see Citrus Oils, page 94.

Bitter almond oil (free from hydrogen cyanide) contains benzaldehyde as its main component. Benzaldehyde does not occur as such in the plant, but is formed, together with hydrogen cyanide, by the hydrolytic cleavage of the

glycoside amygdalin. Amygdalin is present in bitter almonds, the seeds of *Prunus amygdalus* Batsch var. *amara* (DC.) Focke, and ripe apricot kernels, *Prunus armeniaca* L. (Rosaceae). The press cake, which remains after removal of the fatty oils, is macerated with water and left to stand for several hours, after which the "essential oil" is separated by steam distillation. The crude oil contains 2–4 % hydrogen cyanide, which is removed by washing with alkaline solutions of iron(II) salts. Subsequent redistillation yields an oil free from hydrogen cyanide. It is a colorless to slightly yellow liquid with an intense, almond-like, cherry aroma and a slightly astringent, mild taste.

d_{25}^{25} 1.040–1.050; n_D^{20} 1.5410–1.5460; $[\alpha]_D$ 0° to +0°25′; acid value: max. 8; aldehyde content (calculated as benzaldehyde): min. 95 %; solubility: 1 vol in 2 vol of 70 % ethanol [212].

Bitter almond oil is used almost exclusively in natural aroma compositions.

Black currant absolute (Bourgeons de cassis absolute) is obtained by solvent extraction via the concrete obtained from the dormant buds of the black currant bush *Ribes nigrum* L. (Saxifragaceae). The yield is ca. 3 %. Black currant absolute is a dark green paste with the characteristic, powerful, penetrating odor of black currants.

It has been used as a major ingredient in some fine fragrances.

Bois de rose oil, see Rosewood Oil, page 115.

Buchu leaf oils are obtained by steam distillation of *Agathosma betulina* (Bergius) Pillans (syn. *Barosma betulina*) and *A. crenulata (L.)* Pillans (syn. *Barosma crenulata*) (Rutaceae) leaves. The oils are dark yellow to brown liquids with a characteristic minty-fruity odor, reminiscent of black currant.

d_{25}^{25} 0.912–0.956, n_D^{20} 1.474–1.488; $[\alpha]_D$ −36° to −8°; acid value: 1–5; ester value: 20–85.

The bushes grow wild and are cultivated in South Africa. The major components of the oils are (+)-limonene (ca. 10 %) and other cyclic terpenoids that are structurally related to menthone. However, the constituents responsible for the characteristic black currant odor are *p*-menthane-8-thiol-3-one [*38462-22-5*] and its S-acetate derivative [*57074-34-7*] which are two of the small number of naturally occurring sulfur-containing terpenoids known to date [213, 214].

Buchu oil is used as a flavor ingredient (e.g., in fruit aromas) and in perfumery in chypre bases and in certain types of eaux de cologne; only very small amounts are employed because of its intensity.

Calamus oil is obtained by steam distillation of fresh or unpeeled, dried roots of *Acorus calamus* L. (Araceae). It is a yellow to medium brown, moderately viscous liquid with a pleasant, spicy, aromatic odor. (Limiting IFRA recommendation)

The plant occurs in polyploid varieties and the corresponding essential oils differ predominantly in their content of β-asarone (*cis*-isoasarone) [*5273-86-9*]:

diploid (American)	0 %
triploid (European)	0–10 %
tetraploid (Indian)	up to 96 %

β-Asarone

The following data are typical for European and Indian oils, respectively:

d_{25}^{25} 0.940–0.980 and 1.060–1.080; n_D^{20} 1.5010–1.5160 and 1.5500–1.5525; $[\alpha]_D$ +5° to +35° and −2° to +6.5°; acid value: max. 4; ester value: 3–20; solubility: 1 vol in 5 vol of 90 % ethanol; solutions may be turbid [215].

Calamus oil is used in perfumery for spicy-herbaceous notes; small quantities are also employed in the alcoholic beverage industry. However, use is legally restricted because of the potential toxicity of β-asarone.

Camphor oil is obtained by steam distillation of the wood of the camphor tree *Cinnamomum camphora* Sieb. (Lauraceae) growing in China, Taiwan, and Japan. The main constituent of the crude oil is camphor (ca. 50 %), which can be separated by cooling and centrifugation. Fractionation of the mother liquor gives two oils:

1) *White camphor oil* is the first distillation fraction (ca. 20 % of the crude camphor oil). It is a colorless or almost colorless liquid with a cineole-like odor.
   d_{25}^{25} 0.855 – 0.875; n_D^{20} 1.4670 – 1.4720; $[\alpha]_D$ +16° to +28°; solubility: 1 vol in 1 vol of 95 % ethanol; solutions usually become cloudy on further dilution [216].
   In addition to monoterpene hydrocarbons, this oil contains up to 35 % cineole.
   Camphor oils with a higher cineole content can be obtained by further fractionation or by steam distillation of the leaves of other varieties of the camphor tree. They are marketed under the trade name eucalyptus oil 70 – 80 % by Chinese producers, but are not true eucalyptus oils (see Eucalyptus Globulus Oil, page 100).
2) *Brown camphor oil* is a fraction with a boiling point higher than that of camphor (ca. 20 %). It is a pale yellow to brown liquid with the characteristic odor of sassafras oil.
   d_{25}^{25} 1.064 – 1.075; n_D^{20} 1.5100 – 1.5500; $[\alpha]_D$ 0° to +3°; *fp* 6 °C; solubility: 1 vol in 2 vol of 90 % ethanol [217].

The oil contains more than 80 % safrole and, like Brasilian sassafras oil, is therefore used as a raw material for the production of piperonal via isosafrole (see page 69). (IFRA recommendation)

Camphor oils with a high safrole content can also be obtained by steam distillation of the wood of *Cinnamomum parthenoxylon* Nees.

The production of natural camphor and camphor oils was formerly several thousand of tons per year. Nowadays it has declined to 500 t/a as a result of the production of synthetic camphor. The same is true for the distillation of linalool-containing camphor oils (Ho oil, Ho leaf oil), which are derived from other varieties of the camphor tree.

Cananga oil, see Ylang-Ylang and Cananga Oils, page 120.

Caraway oil is obtained by steam distillation of crushed caraway seeds from *Carvum carvi* L. (Apiaceae). It is an almost colorless to amber liquid with a characteristic caraway odor and a mild-spicy taste.

d_{20}^{20} 0.905 – 0.920; n_D^{20} 1.4840 – 1.4890; $[\alpha]_D^{20}$ +67° to +80°; ketone content (calculated as carvone): 50 – 60 %; solubility: 1 vol in 5 vol of 80 % ethanol; acid value: max. 1 [218].

The major constituents of common caraway oil are (+)-limonene and (+)-carvone, which together may make up more than 95 % of the oil. (+)-Carvone is the essential odor component.

Caraway oil is produced mainly in Poland and Hungary. It is used primarily for flavoring foods and alcoholic beverages, but also for the production of (+)-carvone.

Cardamom oil is obtained by steam distillation of the seeds of *Elettaria cardamomum* (L.) Maton var. minuscula Burkill (Zingiberaceae). It is a colorless or very pale yellow liquid with an aromatic, penetrating, slightly camphoraceous odor and a persistent, pungent, strongly aromatic taste.

d_{20}^{20} 0.919 – 0.936; n_D^{20} 1.4620 – 1.4680; $[\alpha]_D^{20}$ +22° to +41°; solubility: 1 vol in 2 to 5 vol of 70 % ethanol, solutions sometimes slightly opalescent [219].

The major components of cardamom oil are 1,8-cineole and α-terpinyl acetate (ca. 30 % each). It is produced from cultivated or wild plants in the mountainous regions of southern India, Sri Lanka, Indonesia, Thailand, southern China, and Guatemala. Cardamom oil is used primarily for seasoning foods and occasionally in perfumery.

Carrot seed oil is obtained by steam distillation of the crushed seeds of *Daucus carota* L. (Apiaceae). It is a light yellow to amber-yellow liquid with a pleasant, aromatic odor.

d_{20}^{20} 0.900 – 0.945; n_D^{20} 1.4800 – 1.4930; $[\alpha]_D^{20}$ – 30° to – 4°; acid value: min. 5.0; ester value: 9 – 58; ester value (after acetylation): 50 – 95; solubility: 1 vol in 2 vol of 80 % ethanol [220].

The main constituent of carrot seed oil is carotol [*465-28-1*], which may be present in over 50 % concentration and is responsible for the characteristic odor.

Carotol

Carrot seed oil is used in the alcoholic beverage industry, in food flavors, and in perfume compositions.

Castoreum, see Animal Secretions, page 87.

Cedar Oils. Several different conifer species are called cedars and the corresponding oils vary considerably in composition. Worldwide annual production is about 800 t. The following cedar oils are commercially important:

1) *Atlas cedarwood oil* is obtained by steam distillation of wood from *Cedrus atlantica* (Endl.) Manetti ex Carr. (Pinaceae). It is a yellowish to brownish, slightly viscous liquid with a sweet aromatic odor and a lasting, woody undertone.
d_{25}^{25} 0.925 – 0.940; n_D^{20} 1.5060 – 1.5160; $[\alpha]_D$ + 50 ° to + 77 °; ketone content (calculated as atlantone): min. 20 %; solubility: 1 vol in at least 5 vol of 95 % ethanol [221].
Atlas cedarwood oil and Himalaya cedarwood oil [from *Cedrus deodara* (D. Don) G. Don] both contain α-atlantone [*32207-08-2*] as their main odoriferous component. They are used mainly in soap perfumes.

E-(+)-α-Atlantone

2) *Cedar leaf oil* (Thuja oil) is produced by steam distillation of fresh leaves and branch ends of the tree *Thuja occidentalis* L. (Cupressaceae). It is a colorless to yellow liquid with a powerful, herbaceous odor, characteristic of thujone [*546-80-5*].
d_{25}^{25} 0.910 – 0.920; n_D^{20} 1.4560 – 1.4590; $[\alpha]_D$ – 14 ° to – 10 °; ketone content (calculated as thujone): min. 60 %; solubility: 1 vol in 3 vol of 70 % ethanol at 25 °C [222].

(–)-Thujone

The oil is produced in the northern states of the United States and in Canada. It is used in perfumery for dry nuances in citrus and woody compositions.

3) *Chinese cedarwood oil* is similar in composition to Texas cedarwood oil (see below). Chinese cedarwood oil is obtained by steam distillation of the wood of *Chamaecyparis funebris* Endl. = *Cupressus funebris* Endl. (Cupressaceae), which is a weeping cypress, indigenous to China [223]. Annual production lies between 850 and 900 t. Chinese cedarwood oil is an almost colorless to light yellow oil with a woody, bitter odor. d_{20}^{20} 0.938 – 0.960; n_D^{20} 1.5000 – 1.5080; $[\alpha]_D^{20}$ – 35 ° to – 20 °; cedrol content: min. 10 %, max. 16 % (by GLC); solubility: 1 vol in 5 vol of 95 % ethanol at 20 °C [224].
4) *Texas cedarwood oil* is produced by steam distillation of chopped wood of the Texas cedar, *Juniperus mexicana* Schiede (Cupressaceae). It is a brown to reddish-brown, viscous liquid that may partially solidify at room temperature. It has a characteristic cedarwood odor.
d_{20}^{20} 0.950 – 0.966; n_D^{20} 1.5020 – 1.5100; $[\alpha]_D^{20}$ – 52 ° to – 30 °; total alcohol content (calculated as cedrol): 35 – 48 %; cedrol content: min 20 % (by GLC), solubility: 1 vol in 5 vol of 90 % ethanol at 20 °C [225].
For uses, see Virginia cedarwood oil.
5) *Virginia cedarwood oil* is produced by steam distillation of sawdust, finely chipped waste wood from the manufacture of cedarwood products, or from stumps and logs of the red cedar; *Juniperus virginiana* L. (Cupressaceae). It is an almost colorless to pale yellow, viscous liquid with a characteristic cedarwood odor. The oil sometimes solidifies at room temperature.
d_{20}^{20} 0.941 – 0.965; n_D^{20} 1.5020 – 1.5100; $[\alpha]_D^{20}$ – 36 ° to – 16 °; solubility: 1 vol in 5 vol of 95 % ethanol; sum of cedrol and widdrol: min. 15 %, max. 30 % (by GLC) [226, 227].

While the Texas cedar grows in Mexico and other Central American countries, the Virginia cedar grows exclusively in the Southeast of the United States. Both cedar oils (production around 1600 t/a) are used mainly for perfuming soaps and other products, as well as a starting material for the isolation of cedrol [*77-53-2*]. Further fragrance substances such as cedryl acetate (see p. page 41) and cedryl methyl ether (see p. page 34) are produced from cedrol. The oils contain other sesquiterpenes, particularly α-cedrene and thujopsene, which can be converted to valuable fragrance materials. By acetylation of the mixture cedryl methyl ketone (see page 39) is produced; for production of ambrocenide pure α-cedrene is used (see page 76).

(+)-Cedrol

Celery seed oil is obtained by steam distillation of the crushed, ripe seeds of celery, *Apium graveolens* L. (Apiaceae). It is an almost colorless to brownish-yellow liquid with a characteristic, pervasive, spicy, very persistent odor.

d_{20}^{20} 0.867 – 0.908; n_D^{20} 1.4780 – 1.4880; $[\alpha]_D^{20}$ +65° to +78°; solubility: 1 vol in no more than 6 vol of 90 % ethanol at 20 °C; acid value: max. 6; ester value: 20 – 70 [228].

Major mono- and sesquiterpene hydrocarbons in the oil are (+)-limonene (58 to 79 % according to ISO) and β-selinene [*17066-67-0*]. Its typical, long-lasting odor is caused primarily by two lactones, 3-butylphthalide [*6066-49-5*] and sedanenolide [*62006-39-7*] which each occur at a concentration of ca. 1 %.

(+)-β-Selinene

3-Butylphthalide

Sedanenolide (3-butyl-4,5-dihydrophthalide)

Celery for the production of seed oil is grown mainly in southern France, India, and California. The seed oil is used chiefly for flavoring foods, although small quantities are also used in perfumery.

Chamomile oils are available in three types:

1) *Blue chamomile oil* (German chamomile oil) is obtained by steam distillation of the flowers and stalks of *Chamomilla recutita* (L.) Rauschert (*Matricaria recutita.* L., *M. chamomilla* L. p.p.-Asteraceae), which is grown mainly in central and eastern Europe, Egypt, and Argentina. Annual production is ca. 10 t. Blue chamomile oil is a deep blue or bluish-green liquid that turns green and, finally, brown when exposed to light and air. The oil has a strong, characteristic odor and a bitter-aromatic taste. Chamazulene [*529-05-5*] is responsible for its blue color. Chamazulene and (−)-α-bisabolol [*23089-26-1*] contribute to the anti-inflammatory properties of blue chamomile oil.

Chamazulene

(−)-α-Bisabolol

d_{25}^{25} 0.910 – 0.950; acid value: 5 – 50; ester value: 0 – 40; ester value (after acetylation): 65 – 155; solubility: solutions in 95 % ethanol usually remain turbid [229].

2) *Roman chamomile oil* (English chamomile oil) is produced from the dried flowers of *Chamaemelum nobile* (L.) All. (*Anthemis nobilis* L.), Asteraceae, which are cultivated primarily in Belgium, but also in England, France, and Hungary. The oil is distilled in France and England. It is a light blue or light greenish-blue liquid with a strong aromatic odor characteristic of the flowers.
d_{20}^{20} 0.900 – 0.920; n_D^{20} 1.4380 – 1.4460; $[\alpha]_D^{20}$ −2° to +3°, acid value: max. 8; ester value: 250 – 340; solubility: 1 vol in 0.6 vol of 90 % ethanol (solutions may contain a slight precipitate) [230].

The constituents of Roman chamomile oil include esters of angelic and tiglic acids.

3) *Moroccan chamomile oil* (wild chamomile oil) is produced from *Ormenis* species (e.g., *O. multicaulis, O. mixta*) that grow wild in Morocco. It is a light yellow liquid with a sweet, herbaceous, woody balsamic odor. Its main constituents are irregular monoterpenes, such as santolina alcohol [*35671-15-9*] and artemisia alcohol [*29887-38-5*].

Santolina alcohol

Artemisia alcohol

Cinnamon oils

1) *Cassia oil* (Chinese cinnamon oil) is obtained by steam distillation of the leaves, leaf stalks, and young twigs, of *Cinnamomum aromaticum* Nees (*C. cassia* Bl., Lauraceae). It is a yellow to reddish-brown liquid with a sweet-spicy, cinnamon-like odor, annual production around 300 t.
d_{20}^{20} 1.052 – 1.070; n_D^{20} 1.6000 – 1.6140; solubility: 1 vol in 3 vol of 70 % ethanol at 20 °C; acid value: max. 15; content of carbonyl compounds (calculated as cinnamaldehyde): min. 80 % [231].
In contrast to cinnamon bark oil, cassia oil contains a considerable amount of 2-methoxycinnamaldehyde (5 to 10 %) in addition to its main constituent, cinnamaldehyde. Cassia oil is used predominantly in flavor compositions. (Limiting IFRA recommendation)

2) *Cinnamon leaf oil* is produced by steam distillation of the leaves of the cinnamon tree, *Cinnamomum zeylanicum* Blume. The main countries in which the oil is produced are Sri Lanka, the Seychelles, southern India, Madagascar, and the Comoro Islands. It is a reddish-brown to dark brown liquid with a characteristic spicy odor, reminiscent of clove buds.
Specifications of cinnamon leaf oil from Sri Lanka are d_{20}^{20} 1.037 – 1.053; n_D^{20} 1.5270 – 1.5400; $[\alpha]_D^{20}$ – 2.5 ° to + 2 °; solubility: 1 vol in 2 vol of 70 % aqueous ethanol at 20 °C; phenol content: 75 – 85 % [232].
The main component of cinnamon leaf oil is eugenol. The oil is used as such or as a source of high-grade eugenol (see page 66).

3) *Sri Lanka cinnamon bark oil* is obtained by steam distillation of the dried bark of the cinnamon tree. It is a yellow liquid with the odor and burned-spicy taste of cinnamon.
d_{25}^{25} 1.010 – 1.030; n_D^{20} 1.5730 – 1.5910; $[\alpha]_D$ – 2 ° to 0 °; aldehyde content (calculated as cinnamaldehyde): 55 – 78 %; solubility: 1 vol in at least 3 vol of 70 % ethanol [233].
The oil is used predominantly in flavor compositions. (Limiting IFRA recommendation)

Cistus oil, see Labdanum Oil, page 104.

Citronella oil, see Cymbopogon Oils, page 98.

Citrus oils comprise both essential oils obtained from the peels of citrus fruits and essence oils obtained by concentrating citrus juice (see Section 3.2.1). The essential oils and the essence oils have similar compositions.

Oils isolated from other parts of citrus plants (blossoms and leaves) are not classified as citrus oils because the former show marked differences in composition and organoleptic properties, they are described in other sections (see Neroli Oil, page 109 and Petitgrain Oils, page 112).

Production of Citrus Peel Oils. Apart from distilled lime oil, citrus peel oils are produced by pressing. Pressing of the peels for oil is often combined with juice production.

In the first industrial production process, the citrus fruit was cut into halves and the juice was then pressed out. Further pressing of the peel liberated the desired oil. This mechanical procedure, which is still used, is known as *cold pressing.* Currently, most citrus peel oils are produced by other methods. For instance, the peel of the whole fruit is rasped or punctured before juice extraction to release the oil. The oil is then rinsed off with water and is subsequently separated from the resulting emulsion by centrifugation.

Production of Citrus Essence Oils. Distillative concentration of citrus juices yields essence oils, which separate from the aqueous phase in the receiver when the distillate condenses. The composition of essence oils is similar to that of

peel oils, but the essence oils usually contain a larger amount of aliphatic ethyl esters (e.g., ethyl butyrate in orange essence oil). Thus, their aroma resembles that of a particular juice more than that of peel oils.

Citrus oils contain up to 95 % monoterpene hydrocarbons (usually limonene, but others as well, e.g., lemon oil also contains α-terpinene and β-pinene). The important aroma-determining components of citrus oils are functionalized terpenes and aliphatic compounds (predominantly carbonyl compounds and esters), present only in very low concentrations. Thus, several methods are employed to concentrate citrus oils on an industrial scale. The monoterpene hydrocarbon content is decreased by distillation, liquid–liquid partitioning between two immiscible solvents, or absorption on a carrier such as silica gel. The deterpenized concentrates are marketed under the name "Citrus oil *x*-fold", depending on the concentration factor.

1) *Bergamot oil, Italian* is obtained by cold-pressing peels from the unripe fruits of *Citrus aurantium* L. subsp. *bergamia* (Risso et Poit.) Wight et Arn. (Rutaceae). It is a green to greenish-yellow liquid, which sometimes contains a deposit. The oil has a pleasant, fresh, sweet, fruity odor.
d_{20}^{20} 0.876 – 0.883; n_D^{20} 1.465 – 1.470; $[\alpha]_D^{20}$ + 15 ° to + 32 °; evaporation residue 4.5 – 6.4 %; solubility: 1 vol in 1 vol of 85 % ethanol at 20 °C; acid value: max. 2.0; ester value: 86 – 129, corresponding to an ester content of 30 – 45 % (calculated as linalyl acetate) [234].
Bergamot is still grown almost exclusively in the Italian province of Calabria, where the soil and climatic conditions are very favorable for its cultivation. The bergamot is grafted onto bitter orange plants. The quality of the oil is determined by its ester content and varies with the species. Annual production is ca. 90 t.
Linalyl acetate, linalool (10 %), and citral (1 %) are important components of bergamot oil. Its terpene content (25 – 50 %) is relatively low for a citrus oil.
Use of the untreated oil in cosmetics is limited by the photosensitizing properties of bergaptene (a furocoumarin) present in the oil, thus an IFRA recommendation exists. Bergamot oil is used in many perfumes and is an important component of eaux de cologne.
2) *Grapefruit oil* is obtained by cold pressing of the outer peels of the fruits of *Citrus paradisi* Macfad. (Rutaceae). It is a yellow to reddish orange liquid, with fresh citrus-like odor characteristic of grapefruit peel.
d_{20}^{20} 0.852 – 0.860; n_D^{20} 1.4740 – 1.4790; $[\alpha]_D^{20}$ + 91 ° to + 96 °; carbonyl value: min. 3.25; evaporation residue: min. 5.0 %, max. 10.0 % [235].
Grapefruit oil is produced mainly in the United States and its composition varies with the species. White grapefruit oil obtained from the varieties Marsh seedless and Duncan that are grown in Florida, contains ca. 90 % terpene hydrocarbons (mainly (+)-limonene), 0.5 % alcohols (mainly linalool), 1.8 % aldehydes (mainly octanal and decanal), 0.5 % ketones (mainly nootkatone), 0.3 % esters (mainly octyl and decyl acetate), and 7.5 % nonvolatile components [236, 237].
The sesquiterpene ketone nootkatone (for structure, see page 39) is primarily responsible for the characteristic aroma of grapefruit oil.
Grapefruit oil is used mainly for flavoring fruit beverages. Annual production is 200 to 220 t. (Limiting IFRA recommendation)
3) *Lemon oil* is obtained by pressing peel from the fruits of *Citrus limon* (L.) Burm. f., (Rutaceae). It is a pale yellow to pale greenish-yellow liquid with a characteristic lemon peel odor. ISO differentiates between American, Mediterranean, and Equatorial type. The American type is subdivided into 'coastal' and 'desert' type. In the following the physical properties of the 'coastal' type are given.
d_{20}^{20} 0.852 – 0.858; n_D^{20} 1.4730 – 1.4760; $[\alpha]_D^{20}$ + 57 ° to + 65.6 °; evaporation residue: 1.75 – 3.6 % [238]; acid value: max. 2 %; content of carbonyl compounds (calculated as citral): 8.0 – 14.0 %.
The composition of lemon oils depends on the variety of lemon and the country of origin. Their main components are terpenes – (+)-limonene (ca. 65 %), β-pinene, and γ-terpinene (8 – 10 % each) being the most important. The characteristic odor of lemon oil differs from that of other citrus oils and is

largely due to neral and geranial. The content of these compounds is in the coastal type between 1.6% and 2.9 %, in Italian lemon oil between 1.4 and 3.2 % [238].

Annual worldwide production is about 3.7×10^3 t, most of which originates from the United States, Italy, and Argentina.

Lemon oil is used in many food flavors. Because of its fresh odor, relatively large quantities are also employed in eaux de cologne and other perfumery products (see IFRA recommendation).

4) *Lime oil* may be either cold-pressed or distilled, but the distilled oil is produced on a much larger scale.

Two varieties of limes are of importance in the commercial production of lime oils: the West Indian (Mexican or Key) lime, *Citrus aurantiifolia* (Christm. et Panz.) Swingle and the Persian (Tahiti) lime, *C. latifolia* Tanaka (Rutaceae). The former has small fruits with many seeds, and the latter bears larger, seedless fruits. West Indian limes are grown primarily in Mexico, the West Indies and Peru; Persian limes are cultivated in Florida and Brazil.

Persian lime oils contain lower concentrations of the typical organoleptic components than the West Indian lime oils and are thus comparatively mild and flat [239]. Consequently, West Indian lime oils are more popular.

*Pressed lime oils*are obtained by rasping and puncturing (type B). Other methods are also employed for West Indian limes: the whole fruits may be chopped and the oil–juice emulsion subsequently centrifuged (type A) [240,241].

Pressed lime oil (Mexican type, A) is a yellowish green liquid with a strong, characteristic odor, reminiscent of lemon. Limiting IFRA recommendation.

Type A: d_{20}^{20} 0.875 – 0.884, n_D^{20} 1.482 – 1.486, $[\alpha]_D^{20}$ + 35 ° to + 42 °; carbonyl value: min. 16, max. 31, corresponding to 4.5 to 8.5 % of carbonyl compounds expressed as citral; evaporation residue: 10.0 – 14.5 % [242].

Cold-pressed lime oils are produced in a quantity of about 300 t/a. The composition and uses of pressed lime oil are similar to those of pressed lemon oil.

Distilled lime oils are produced by steam distillation of an oil–juice emulsion that is obtained by chopping the whole fruit. The acid present in the juice acts on the oil released from the peel and changes its characteristics. The original components are modified to form a series of new compounds.

Distilled lime oil is a colorless to pale yellow liquid, with a characteristic odor, which differs from that of the fresh fruit and the cold-pressed oil.

d_{20}^{20} 0.856 – 0.865; n_D^{20} 1.474 – 1.478; $[\alpha]_D^{20}$ + 34 ° to + 45 °; evaporation residue: max. 2.5 %; content of carbonyl compounds (calculated as citral): max. 1.5 % [243].

Acid-catalyzed cyclization and dehydration of citral and linalool give rise to several compounds that occur at comparatively high concentrations and contribute to the typical aroma of distilled lime oil (e.g., 1,4-cineole [*470-67-7*], 1,8-cineole [*470-82-6*], 2,2,6-trimethyl-6-vinyltetrahydropyran [*7392-19-0*], and 2-(2-buten-2-yl)-5,5-dimethyltetrahydrofuran [*7416-35-5*]).

Annual worldwide production of distilled West Indian lime oil is about 750 t. The oil is used primarily in soft drinks.

5) *Mandarin oil* is obtained by cold pressing the peel of mandarin oranges, the fruits of *Citrus reticulata* Blanco (Rutaceae). The oil is a greenish-yellow to reddish-orange liquid, depending on the degree of ripeness of the fruit, with a pale blue fluorescence and a characteristic odor, reminiscent of mandarin peel.

d_{20}^{20} 0.848 – 0.855; n_D^{20} 1.474 – 1.478, $[\alpha]_D^{20}$ + 64 ° to + 75 °; evaporation residue: 1.6 – 4.0 %; content of carbonyl compounds (calculated as decanal): 0.4 – 1.2 %; acid value: max. 2.0 [244].

The main components are limonene (ca. 70 %) and γ-terpinene (ca. 20 %). The characteristic feature of mandarin oil is its content of α-sinensal, methyl *N*-methylanthranilate (which is responsible for fluorescence), and long-chain unsaturated aliphatic aldehydes.

Annual production of mandarin oil in Italy is ca. 100 t; smaller quantities are produced in Spain, Brazil, and Argentina.

Mandarin oil is used to enrich the bouquet of flavor compositions containing sweet orange

oils as the main component. It is also used in liqueurs and perfumery.

6) *Orange oil bitter* is obtained by pressing fresh peel from the fruits of *Citrus aurantium* L. subsp. *aurantium* (Rutaceae). It is produced mainly in Mediterranean countries and is a pale yellow to yellowish-brown liquid with a slightly mandarin-like odor and a somewhat bitter aroma.
d_{20}^{20} 0.8480 – 0.8600; n_D^{20} 1.4720 – 1.4760; $[\alpha]_D^{20}$ +88° to +98°; evaporation residue: 2 – 5 %; aldehyde content (calculated as decanal): min. 0.5 %, max. 2.9 % [245].
The composition of bitter orange oil differs from that of sweet orange oil; i.e., its aldehyde content is lower and its ester content is higher.
Worldwide production of bitter orange oil (ca. 10 t/a) is lower than that of other pressed peel oils. Bitter orange oil is used in eaux de cologne and liqueurs. Limiting IFRA recommendation.

7) *Orange oil sweet* is obtained from the peel of the fruits of *Citrus sinensis* (L.) Osbeck. It is a yellow to reddish-yellow liquid with the characteristic odor of orange peel and may become cloudy when chilled. Sweet orange oil is often produced in combination with orange juice (e.g., in the United States, Brazil, Israel, and Italy). Specifications for the oils depend on the cultivated varieties and the country of origin [246]
The ISO specification of Orange oil sweet is as follows:
d_{20}^{20} 0.842 – 0.850; n_D^{20} 1.4700 – 1.4760; $[\alpha]_D^{20}$ +94° to +99°; evaporation residue: 1.0 – 5.0 %; content of carbonyl compounds (calculated as decanal): 0.9 – 3.1 %.
The oils have a high terpene hydrocarbon content (> 90 %, mainly (+)-limonene), but their content of oxygen-containing compounds differs and affects their quality. Important for aroma are aldehydes, mainly decanal and citral, and aliphatic and terpenoid esters. The sesquiterpene aldehydes α-sinensal [*17909-77-2*] and β-sinensal [*6066-88-8*], which contribute particularly to the special sweet orange aroma, also occur in other citrus oils, although in lower concentration.
Worldwide production of cold-pressed orange oil is over 27 000 t/a. Its main uses are the flavoring of beverages and confectioneries and perfuming eaux de cologne, soap, and household products.

α-Sinensal β-Sinensal

Civet, see Animal Secretions, page 87.

Clary sage oil, see Sage Oils, page 115.

Clove oils are produced from the 15 – 20-m high clove tree *Syzygium aromaticum* (L.). Merr. et L. M. Perry, syn: *Eugenia caryophyllus* (Spreng.) Bullock ex S. G. Harrison (Myrtaceae).

1) *Clove bud oil* is obtained in 15 – 20 % yield by steam distillation of the dried flower buds. Clove bud oil, like the leaf oil, is a yellow to brown, sometimes slightly viscous liquid. It turns dark purple-brown on contact with iron. The oil has the spicy odor characteristic of eugenol.
d_{20}^{20} 1.042 – 1.063; n_D^{20} 1.5280 – 1.5380; $[\alpha]_D^{20}$ −1.5° to 0°; solubility: 1 vol in 2 vol of 70 % ethanol at 20 °C; phenol content: min. 85 %, max. 93 % [247].

2) *Clove leaf oil* is obtained in 2 – 3 % yield by steam distillation of the leaves of the abovementioned.
d_{20}^{20} 1.039 – 1.049; n_D^{20} 1.5280 – 1.5350; solubility: 1 vol in 2 vol of 70 % ethanol at 20 °C; phenol content: minimum 82 % [248].
The main component of all clove oils is eugenol (draft for a GLC specification for leaf oils: 80 to 92 %), which is responsible for their odor and antiseptic properties. Other major constituents are eugenyl acetate and caryophyllene. Clove bud oil has a higher acetate content and a more delicate odor than leaf oil, but is much more expensive than the leaf oil. Leaf oil is produced and used in the largest quantities.
The most important countries that produce clove oils are Madagascar, Tanzania, and Indonesia. Smaller quantities are produced in

other tropical areas (e.g., Malaysia and Sri Lanka). Worldwide production of clove oils is 2000 – 2200 t/a, of which Indonesia produces about half.

The oils are used in many perfume and aroma compositions, because of their spicy clove odor. A small amount is used as an antiseptic, mainly in dentistry. The leaf oil, in particular, is also used as a raw material for the production of eugenol, which is the starting material for further commercially important fragrance compounds, such as isoeugenol and eugenyl esters (see page 65).

Copaiba (balsam) oils are obtained by steam distillation of the exudate (balsam) from the trunk of several species of *Copaifera* L. (Fabaceae), a genus of trees growing in the Amazon basin. They are colorless to light yellow liquids with the characteristic odor of the corresponding balsams and an aromatic, slightly bitter, pungent taste.

d_{25}^{25} 0.880 – 0.907, n_D^{20} 1.4930 – 1.5000; $[\alpha]_D$ – 33 ° to – 7 °; solubility: 1 vol in 5 – 10 vol of 95 % ethanol [249].

The oils consist primarily of sesquiterpene hydrocarbons; their main component is caryophyllene (> 50 %, for formula, see Section 2.3).

Copaiba balsam oils and balsams are used mainly as fixatives in soap perfumes.

Coriander oil is obtained by steam distillation of ripe fruits of *Coriandrum sativum* L. (Apiaceae). It is an almost colorless to pale yellow liquid with a characteristic spicy odor, reminiscent of linalool.

d_{20}^{20} 0.862 – 0.878; n_D^{20} 1.4620 – 1.4700; $[\alpha]_D^{20}$ + 7 ° to + 13 °; solubility: 1 vol in 8 vol of 65 % ethanol at 20 °C; acid value: max. 3.0; linalool content by chromatography: min. 68 % [250].

The main component of coriander oil is (+)-linalool (60 – 80 %). Mono- and polyunsaturated fatty aldehydes, although minor components, contribute to the characteristic aroma of the oil because of their powerful odor.

Coriander is mainly cultivated in the CIS, Poland, and Hungary. Worldwide oil production is 50 – 100 t/a. Coriander oil is no longer important as a raw material for the production of linalool and its derivatives. However, it is still used extensively in seasoning mixtures and in perfume compositions.

Cornmint oil, see Mint Oils, page 107.

Cumin oil is obtained by steam distillation of ripe fruits of *Cuminum cyminum* L. (Apiaceae). It is a light yellow to brown liquid with a strong, somewhat fatty and green odor.

d_{20}^{20} 0.905 – 0.930; n_D^{20} 1.490 – 1.5060; $[\alpha]_D^{20}$ + 1 ° to + 8 °; solubility: 1 vol in 8 vol of 80 % ethanol at 20 °C; aldehyde content: 45 – 58 % (calculated as cuminaldehyde) [251].

Cymbopogon oils are produced from several aromatic grasses that belong to the genus *Cymbopogon* Spreng. (Poaceae). The oils are obtained by steam distillation of the parts of the plants that grow above ground. The following oils are of commercial interest:

1) *Citronella oil* is available in two types:
   a) *Ceylon or Sri Lanka citronella oil* is produced by steam distillation of fresh or partly dried leaves and stems of the grass species *Cymbopogon nardus* (L.) W. Watson–"lenabattu"–cultivated in Sri Lanka. It is a pale yellow to brownish liquid with a fresh, grassy, camphoraceous odor.
   d_{20}^{20} 0.891 – 0.910; n_D^{20} 1.479 – 1.490; $[\alpha]_D^{20}$ – 25 ° to – 12 °; solubility: 1 vol in 2 vol of 80 % ethanol at 20 °C; ester value (after acetylation): 157 – 200; carbonyl value: 18 – 55, corresponding to 5 – 15 % carbonyl compounds (calculated as citronellal) [252].
   Ceylon oil is less valuable than Java oil and is used almost exclusively for perfuming toilet soaps, washing powders, and household products.
   b) *Java citronella oil* is obtained by steam distillation of fresh or partially dried stems and leaves of *Cymbopogon winterianus* Jowitt syn. *Cymbopogon nardus* W. Watson var. mahapengiri Winter, which is grown in Southeast Asia, India, and Indonesia, as well as in Central and South America. It is a pale yellow to pale yellowish brown liquid with a slightly sweet, flowery, roselike odor with the strong citrus note of citronellal.

d_{20}^{20} 0.880 – 0.893; n_D^{20} 1.467 – 1.473; $[\alpha]_D^{20}$ $-5°$ to $0°$; solubility: 1 vol in 2 vol of 80 % ethanol at 20 °C, opalescence is sometimes observed when ethanol is continuously added; ester value (after acetylation): min. 250, corresponding to 85 % acetylizable compounds (calculated as geraniol, this percentage includes citronellal, since it is converted quantitatively into isopulegyl acetate under the acetylation conditions); carbonyl value: min. 127, corresponding to 35 % carbonyl compounds (calculated as citronellal) [253].

Java citronella oil may contain up to 97 % acetylizable compounds and up to 45 % carbonyl compounds, depending on the time of harvesting. Is is used extensively not only in perfumery, but also as one of the most important raw materials for the production of citronellal. In addition, a fraction with a high geraniol content is obtained from the oil. Both citronellal (see page 22) and the geraniol fraction (see page 15) are starting materials for the synthesis of a large number of other fragrance compounds. The oil produced in Taiwan and in Java contains, in addition to the major components citronellal and geraniol, 11 – 15 % citronellol, 3 – 8 % geranyl acetate, 2 – 4 % citronellyl acetate, and many other minor components.

Annual worldwide production was reported to be > 5000 t in 1971 and is now less than 2000 t. Main producers are Taiwan, China (province of Hainan), and Java [254].

2) *Lemongrass oil* is available in two types, which are produced by steam distillation.
   a) *West Indian or Guatemala lemongrass oil* is obtained from *Cymbopogon citratus* (DC.) Stapf in Central and South America, as well as in a number of African and East Asian countries. It is a pale yellow to orange-yellow liquid with a lemon-like odor, characteristic of citral.
   d_{20}^{20} 0.872 – 0.900; n_D^{20} 1.483 – 1.489; $[\alpha]_D^{20}$ $-6°$ to $0°$; content of carbonyl compounds (calculated as citral): min. 75 %; solubility: freshly distilled oil is soluble in 70 % ethanol at 20 °C, but solubility diminishes on storage and the oil may become insoluble in 90 % ethanol. Residues remain after vacuum distillation of oils stored for longer times due to the high molecular mass products formed by polymerization of myrcene. The oil contains up to 20 % myrcene [255].
   b) *Indian lemongrass oil* is obtained from the so-called Indian variety of lemongrass, *Cymbopogon flexuosus* (Nees ex Steud.) Stapf. The oil is produced mainly in India. Its physical constants differ slightly from those of the West Indian type, the main difference being in the density, which is d_{20}^{20} 0.885 – 0.905 [256].

   The two oils were formerly the main source of natural citral, obtained as a ca. 4 : 1 mixture of geranial and neral by distillation (see page 21). However, lemongrass oil has declined in commercial importance due to the competitive synthesis of citral (see page 21) and isolation of natural citral from Litsea cubeba oil (see page 106). Nevertheless, between 300 and 500 t/a are still produced. In addition to being processed into citral, it is used to some extent for perfuming soap and household products.

3) *Palmarosa oil* is obtained by steam distillation of wild or cultivated *Cymbopogon martinii* (Roxb.) W. Watson. var. *motia,* collected when in blossom. It is a pale yellow liquid with a characteristic roselike odor and a grassy note.

   d_{20}^{20} 0.880 – 0.894; n_D^{20} 1.4710 – 1.4780; $[\alpha]_D^{20}$ $-1.4°$ to $+3°$; solubility: 1 vol in 2 vol of 70 % ethanol at 20 °C; acid value: max. 1.0; the following data are valid for oil from India, oils of other origin possess slightly different data, ester value: min. 7, max. 36; ester value (after acetylation): 260 – 280, corresponding to a total alcohol content of 88 – 95 %, free alcohol content (calculated as geraniol): 74 – 94 % [257]. High-grade palmarosa oil may contain up to 95 % geraniol and its esters; it is produced in smaller quantities than other oils obtained from aromatic grasses. Annual worldwide production is ca. 150 t. Palmarosa oil is the starting material for geraniol and geranyl esters of high odor quality, but it is also used for perfuming soaps and cosmetics.

4) *Gingergrass oil* is produced in India from the *sofia* variety of *Cymbogon martinii* and is less important than palmarosa oil.

Cypress oil is produced by steam distillation of terminal branches of *Cupressus sempervirens* L. (Cupressaceae). It is a liquid with a woodlike odor that has an ambergris note.

d_{20}^{20} 0.863 – 0.885; n_D^{20} 1.468 – 1.478; $[\alpha]_D^{20}$ + 15 ° to + 30 °; solubility: 1 vol in 8 vol of 90 % ethanol.

This oil is produced exclusively in southern France and Algeria (ca. 10 t/a); its major components are α-pinene and 3-carene. Degradation products of higher terpenoids are responsible for the typical ambergris note [258, 259].

Davana oil is obtained by steam distillation of the herb *Artemisia pallens* Wall. (Asteraceae), grown in south India. It is an orange-brown liquid with a sweet tealike odor reminiscent of dried fruits. The composition of the oil is very complex; its main components are furanoid sesquiterpenes. It is used predominantly for aroma compositions.

Dill oil is obtained from the dill plant, *Anethum graveolens* L. (Apiaceae), in two different forms:

1) *Dill weed oil* is prepared from flowering dill by steam distillation. Its main components are α-phellandrene (up to 60 %) and the so-called (+)-dill ether [*74410-10-9*] (up to 30 %). The latter is responsible for the typical organoleptic properties of the dill plant and, thus, of dill weed oil.

(+)-Dill ether

2) *Dill seed oil* is prepared by steam distillation of the crushed ripe fruits of the dill plant. Its main components are limonene (up to 40 %) and (+)-carvone (up to 60 %). This oil has a typical caraway odor and taste in contrast to the weed oil, which contains only a small amount of carvone.

Commercially available dill oils are mixtures of both types, because the plants are harvested not according to the criteria for the special oils, but when the state of ripeness guarantees a maximum yield. They generally contain α-phellandrene (10 – 20 %), limonene (30 – 40 %), dill ether (3 – 10 %), and carvone (30 – 40 %).

The main growing areas are the Balkan states, Hungary, and the United States. Dill oils are used primarily for seasonings in the pickling and canning industries.

Elemi oil, Elemi resinoid are obtained from exuded gum resin of *Canarium luzonicum* (Miq.) (Burseraceae), a tree growing in the Phillipines. The resin is extracted with a solvent to form the resinoid, which is a yellow to orange mass of high viscosity. The oil is produced by steam distillation of the gum oleoresin and is a colorless to light yellow liquid.

d_{20}^{20} 0.850 – 0.910; n_D^{20} 1.4720 – 1.4900; $[\alpha]_D^{20}$ + 44 ° to + 85 ° [260].

The major components of elemi oil are limonene, α-phellandrene, and the sesquiterpene alcohol elemol. Both the resinoid and the oil have a fresh, citrus-like, peppery odor and are used predominantly in soap perfumes.

Estragon oil, see Tarragon Oil, page 117.

Eucalyptus oils are produced from plants belonging to the genus *Eucalyptus* (Myrtaceae), which includes ca. 500 species in Australia, the country of origin, alone. Correct botanical classification was possible only by determining the chemical composition of the essential oils obtained from the leaves. At present, few of these oils are commercially important.

1) *Cineole-rich Eucalyptus oils*
   a) *Australian eucalyptus oil* is obtained by steam distillation of the foliage of certain Eucalyptus species indigenous to Australia, e.g., from *Eucalyptus fruticetorum* F.v. Muell. (*E. polybractea* R. T. Bak.), *E. smithii* R. T. Bak., and *E. leucoxylon* F.v. Muell.
   d_{20}^{20} 0.918 – 0.928; n_D^{20} 1.458 – 1.465; $[\alpha]_D^{20}$ – 2 ° to + 2 °; solubility: 1 vol in 3 vol of 70 % ethanol at 20 °C; 1,8-cineole content: 80 – 85 % [261].
   The minor components of this oil differ from those of *E. globulus* oil.

b) *Eucalyptus globulus oil* is produced by steam distillation of the leaves and twigs, recently collected of *Eucalyptus globulus* Labillardière. It is an almost colorless to pale yellow liquid with a fresh odor, characteristic of 1,8-cineole. The crude oil contains ca. 65 % cineole and more than 15 % α-pinene. Commercially available qualities are rectified, and have a cineole content of 70 – 75 % or 80 – 85 %. The respective specifications of these two types are as follows:
d_{20}^{20} 0.904 – 0.920 and 0.906 – 0.920; n_D^{20} 1.460 – 1.468 and 1.458 – 1.465; $[\alpha]_D^{20}$ 0 ° to + 10 ° and + 2 ° to + 10 °; solubility 1 vol in 5 vol of 70 % ethanol and 1 vol in 5 vol of 80 % ethanol at 20 °C [262].
The oil is produced mainly in Spain and Portugal, where the wood is used in the cellulose industry, and in China. Worldwide production is between 3500 and 4000 t/a. Eucalyptus oils with a high cineole content are used for cineole production (see page 72). The oils and cineole itself are used primarily in pharmaceutical preparations. Fairly large quantities are also used in perfumery, e.g., to imitate the odor of cineole-containing essential oils. Distillation fractions of camphor oil (see page 90) are also marketed as eucalyptus oils with a cineole content of 70 – 80 %.

Eucalyptus citriodora oil is obtained by steam distillation of leaves and twigs of *Eucalyptus citriodora* Hook. It is an almost colorless, pale yellow, or greenish-yellow liquid with a citronellal-like odor.
d_{20}^{20} 0.860 – 0.870; n_D^{20} 1.450 – 1.456; $[\alpha]_D^{20}$ − 1 ° to + 3 °; solubility: 1 vol in 2 vol of 80 % ethanol at 20 °C; carbonyl value (calculated as citronellal): min. 70 % [263].
In addition to the main component, citronellal, the oil contains citronellol and isopulegol (5 – 10 % each).
Young *E. citriodora* trees that are grown exclusively for essential oil production are cut back to a height of 1 – 1.50 m and develop into shrubs. The leaves can be harvested throughout the year; more than 200 kg of oil can be obtained per hectare.
The major producer is Brazil with over 500 t/a, but considerable quantities are also produced in other countries (e.g., South Africa and India). The annual production worldwide is about 1300 t. *Eucalyptus citriodora* oil is a starting material for the manufacture of citronellal and products derived from it. It is also used in perfumery for the same purposes as citronellal (see page 22).

3) *Eucalyptus dives oil* is obtained by steam distillation of fresh leaves of *Eucalyptus dives* var. *Schau, Typus,* grown in New South Wales.
d_{15} 0.889 – 0.910; n_D^{20} 1.477 – 1.481; $[\alpha]_D^{20}$ − 75 ° to − 50 °; content of carbonyl compounds (calculated as piperitone): 40 – 50 % [264].
In addition to (−)-piperitone (for formula see page 30), the oil contains 15 – 25 % α- and β-phellandrene. The oil was previously used as a starting material in the manufacture of (−)-menthol, but has lost much of its significance. Annual worldwide production in 2002 has dropped to 50 t.

4) *Eucalyptus staigeriana oil* is produced by steam distillation of the leaves of *Eucalyptus staigeriana* F. v. Muell. It has a fresh, lemon-like odor and contains ca. 30 % citral. Further constituents are geraniol and nerol and their acetates, as well as (−)-limonene. It is used mainly in perfumery [265].

Fennel oil is commercially available in sweet and bitter types that are obtained from two varieties of a subspecies of common fennel, *Foeniculum vulgare* Mill., subsp. *capillaceum* Gilib. (Apiaceae). The sweet oil is obtained from the *dulce* variety and the bitter oil from the variety *vulgare* (Mill.) Thell.

The oils are produced both in the Mediterranean countries and in other continents and are obtained by steam distillation of crushed fennel seeds. They are colorless to pale yellow liquids with a typical fennel odor and a camphoraceous, initially sweet taste that later becomes bitter.

d_{20}^{20} 0.961 – 0.977; n_D^{20} 1.5280 – 1.5430; $[\alpha]_D^{20}$ + 11 ° to + 24 °; *fp* 3 – 11.5 °C; solubility: 1 vol in 5 vol of 80 % ethanol.

Both oils are similar in composition; their major components are *trans*-anethole (> 80 % in sweet fennel oil) and fenchone (up to ca. 25 % in bitter fennel oil). Sweet fennel oil is more important because of its higher anethole content. While both oils are used in flavors, small quantities are also employed in perfumery.

Fir needle oils, see Pinaceae Oils, page 113.

Galbanum oil and galbanum resinoid are produced from the gumlike exudate of *Ferula galbaniflua* Boiss. and Buhse (Apiaceae) growing in northern Iran and *F. rubricaulis* Boiss. growing in southern Iran.

The gum is collected from a cut in the upper part of the uncovered roots. The annual yield of gum is ca. 100 t.

The oil is produced by steam distillation and is a colorless to light yellow liquid with a green, slightly spicy odor.

d_{20}^{20} 0.8670 – 0.8900; n_D^{20} 1.4780 – 1.4850; $[\alpha]_D^{20}$ +7° to +17°; acid value: max. 2; solubility: 1 vol in at least 6 vol of 90 % ethanol [266].

In addition to 75 % monoterpene hydrocarbons and ca. 10 % sesquiterpene hydrocarbons, galbanum oil contains a fairly large number of terpene and sesquiterpene alcohols and their acetates. Minor components, with entirely different structures and low odor threshold values, contribute strongly to the chacteristic odor. Examples are as follows:

(*E,Z*)-1,3,5-Undecatriene [*51447-08-6*]

2-Methoxy-3-isobutylpyrazine [*24683-00-9*]

S-sec-Butyl 3-methyl-2-butenethioate [*34322-09-3*]

Galbanum oil is used for creating green top notes in perfume compositions.

Galbanum resinoid is produced by extraction of the gum with a nonpolar solvent. It is used for the same purposes as the oil and has excellent fixative properties.

Geranium oil is obtained by steam distillation of the flowering herb *Pelargonium graveolens* l'Heritier ex Aiton, *P. roseum* Willdenow, and other nondefined hybrids that have developed into different ecotypes in different geographical regions. The oil is an amber to greenish-yellow liquid with the characteristic roselike odor of the plant.

The main cultivation areas are Réunion and Madagascar (Bourbon type), Morocco and Egypt (North African type), and China. The Bourbon quality is more valuable and thus more expensive. Annual worldwide production is ca. 300 t. Specifications of geranium oils [267] are given in Table 3.

The composition of the Bourbon oil differs quantitatively as well as qualitatively from that of North African oil. However, they both contain an unusually high percentage of (−)-citronellol, isomenthone, formates, and tiglates, which are rarely found in essential oils. The two types of oil can be differentiated by two characteristic minor constituents: the Bourbon type contains (−)-6,9-guaiadiene [*36577-33-0*] and the African type contains 10-*epi*-γ-eudesmol [*15051-81-7*] (for structure see page 86). The Chinese type also contains (−)-6,9-guaiadiene, however a smaller amount of menthone/isomenthone and a higher amount of (−)-citronellol than the Bourbon type.

Table 3. Specifications of geranium oils

Parameter	Type of geranium oil			
	Bourbon	Egyptian	Moroccan	Chinese
d_{20}^{20}	0.884 – 0.892	0.887 – 0.892	0.883 – 0.900	0.882 – 0.8
n_D^{20}	1.4620 – 1.4680	1.4660 – 1.4700	1.4640 – 1.4720	1.4600 – 1
$[\alpha]_D^{20}$	−14° to −8°	−12° to −8°	−13° to −8°	−14° to −8°
Solubility in 70 % ethanol (20 °C), vol : vol	1 : 3	1 : 2.2	1 : 3	1 : 5
Acid value (max.)	10	6	10	10
Ester value	52 – 78	42 – 58	35 – 80	55 – 75
Ester value (after acetylation)	205 – 230	210 – 222	192 – 230	215 – 232
Content of carbonyl compounds (as isomenthone), %	max. 16	max. 16	max. 16	max. 10
Alcohol content (as citronellol), %	42 – 55	40 – 58	35 – 58	

(−)-6,9-Guaiadiene

Geranium oil is one of the most important natural raw materials in the fragrance industry. It is used for creating rosy notes, especially in soap.

Ginger oil and ginger oleoresin are produced from the ginger plant *Zingiber officinale* (L.) Rosc. (Zingiberaceae).

Ginger oil is produced by steam distillation of dried, ground rhizomes. It is a light yellow to yellow liquid with the aromatic, persistent odor of ginger, but lacking the pungency usually associated with ginger. The citrus note of ginger oil is due to traces of citral.

d_{25}^{25} 0.871 – 0.882; n_D^{20} 1.4880 – 1.4940; $[\alpha]_D$ − 45 ° to − 28 °; saponification value: max. 20; soluble in ethanol, solutions are usually turbid [268].

The major components of the oil are β-sesquiphellandrene [*20307-83-9*] (about 15 %) and zingiberene [*495-60-3*] (30 to 40 %).

β-Sesquiphellandrene

Zingiberene

Ginger oleoresin is prepared by extracting ginger rhizomes with acetone or alcohol. The product contains the essential oil along with the substances responsible for the pungency of ginger. These compounds are substituted phenols of the following structure:

Gingerols: $R = -CH_2-\underset{\underset{OH}{|}}{CH}-(CH_2)_n-CH_3$; $n = 1–4, 8, 10$

Shogaols: $R = -CH=CH-(CH_2)_n-CH_3$; $n = 2, 4, 6, 8$

Main cultivation areas for ginger are India, Malaysia, Taiwan, and the Fiji Islands. Ginger concentrates are used in large amounts in beverages (e.g., ginger ale), as well as in baked goods and confectioneries.

Grapefruitoil, see Citrus Oils, page 94.

Green cognac oil, see Lie de Vin Oil, page 106.

Guaiac wood oil is obtained by steam distillation of ground wood and sawdust from the tree *Bulnesia sarmienti* Lorentz (Zygophyllaceae), which is up to 20 m high and grows wild in the Gran Chaco region of Paraguay and in Argentina. The annual production is ca. 150 t. The oil is a dark yellowish, viscous liquid with a mild, pleasant odor reminiscent of that of tea roses and faintly of violets. The oil solidifies at room temperature to a yellow-white to light amber colored mass (*mp* 40 – 50 °C).

d_{25}^{25} 0.960 – 0.975; n_D^{20} 1.5020 – 1.5070; $[\alpha]_D$ − 12 ° to − 3 °; solubility: 1 vol in at least 7 vol of 70 % ethanol; solutions are sometimes slightly turbid or opalescent; total alcohol content (calculated as guaiol): min. 85 % [269].

The main constituents of the oil are the sesquiterpene alcohols guaiol [*489-86-1*] and bulnesol [*22451-73-6*]. The oil may be used as a starting material for the synthesis of guaiazulene, which has anti-inflammatory properties.

Guaiol

Bulnesol

Guaiac wood oil is used extensively in perfume compositions for its excellent fixative properties. Also the acetates of the sesquiterpene alcohols of this oil are used in perfumery.

Gurjun balsam oil is produced by steam distillation of balsams obtained from several *Dipterocarpus* species (Dipterocarpaceae); the trees grow in South and East Asia. The oil is a yellow, slightly viscous liquid with a weak, woodlike odor.

d_{15} 0.918 – 0.930; n_D^{20} 1.5010 – 1.5050; $[\alpha]_D$ – 130° to – 35°; solubility: 1 vol in 10 vol of ethanol.

It consists almost entirely of sesquiterpene hydrocarbons, and its main component (> 60 %) is α-gurjunene [*489-40-7*].

α-Gurjunene

Gurjun balsam oil and gurjun balsams are used for their good fixative properties, e.g., in soap perfumes and serve also as a starting material for the production of guaiazulene.

Jasmin absolute is obtained by solvent extraction, via the concrete, from the flowers of *Jasminum grandiflorum* L. (Oleaceae), cultivated in Egypt, Italy, Morocco, and India, and of *J. sambac* (L.) Ait. from China and India. The concrete is usually a brown to dark brown waxy mass, with a characteristic jasmin odor.

mp 48 – 51 °C; ester value: 70 – 125.

The absolute is generally a reddish-brown liquid with a delicate jasmin odor; the color deepens on storage.

n_D^{20} 1.4780 – 1.4920; acid value: 8 – 14; ester value: 120 – 220.

One ton of jasmin blossoms yields ca. 2.5 – 3 kg of concrete when it is extracted two or three times with hexane or benzene. Extraction of the concrete with ethanol gives a ca. 60 % yield of the absolute.

The main volatile component of jasmin oil is benzyl acetate. However, minor components such as indole [*120-72-9*], *cis*-jasmone [*488-10-8*], and methyl jasmonate [*1211-29-6*] contribute strongly to the typical jasmin fragrance.

cis-Jasmone

Methyl jasmonate

The absolute is one of the most valuable blossom fragrances used in fine fragrances.

Juniper berry oil is obtained by steam distillation of berries of *Juniperus communis* L. var. *erecta* Pursh. (Cupressaceae). It is a colorless, pale green or yellowish liquid with a characteristic, conifer-like odor, and an aromatic-bitter taste.

d_{20}^{20} 0.857 – 0.872; n_D^{20} 1.4710 – 1.4830; $[\alpha]_D^{20}$ – 15° to 0°; solubility: 1 vol in 10 vol of 95 % ethanol, solutions usually turbid; acid value: max. 2; ester value: min. 12 [270].

The slightly turpentine-like odor and the relatively low solubility of the oil are caused by its high content of α-pinene and other monoterpene hydrocarbons. The main oxygen-containing component is 1-terpinen-4-ol.

Most juniper berries are obtained from bushes growing in European countries, such as Italy, Czech Republic, Slovakia, Hungary, and former Yugoslavia.

The oil is used to a limited extent in perfumery for creating fresh, dry effects and as an aroma ingredient in alcoholic beverages of the gin type.

Labdanum absolute and Labdanum oil are obtained from labdanum gum, which is exuded when twigs of *Cistus ladaniferus* L. (Cistaceae) are boiled in water.

Labdanum absolute is produced by extraction of the gum with alcohol (e.g., methanol or ethanol). So-called colorless absolutes are obtained from absolutes by extraction with, for example, hexane.

Steam distillation of the gum yields *labdanum oil* which is a golden yellow, viscous liquid that quickly turns dark brown on standing:

d_{25}^{25} 0.905 – 0.993; n_D^{20} 1.4920 – 1.5070; $[\alpha]_D$ + 0° 15′ to + 7°, often difficult to determine due to its dark color; solubility: 1 vol in 0.5 vol of 90 % ethanol, solutions frequently opalescent to turbid, paraffins may separate upon further dilution; acid value: 18 – 86; ester value: 31 – 86 [271].

Other odoriferous materials are derived from the leaves and young twigs of *Cistus ladaniferus.* Cistus oil is obtained by steam distillation; solvent extraction yields cistus concrete. Cistus oil, in contrast to labdanum oil, consists mainly of monoterpene hydrocarbons.

Cistus and labdanum products come from Mediterranean countries, mainly Spain, where the *Cistus* shrub grows abundantly. They are used widely in perfumery, giving perfume compositions a warm, balsamic tonality with a touch of ambergris. The resinoids and absolutes are excellent natural fixatives.

Laurel leaf oil is obtained by steam distillation of leaves from *Laurus nobilis* L. (Lauraceae), an evergreen tree cultivated primarily in Mediterranean countries. The oil is a light yellow to yellow liquid with an aromatic, spicy odor.

d_{25}^{25} 0.905 – 0.929; n_D^{20} 1.4650 – 1.4700; $[\alpha]_D$ $-19°$ to $-10°$; solubility: 1 vol in at least 1 vol of 80 % ethanol; acid value: max. 3; saponification value: 15 – 45; saponification value (after acetylation): 36 – 85 [272].

The main component of the oil is 1,8-cineole (30 – 70 %); other important components are linalool (ca. 10 %) and eugenol.

Laurel leaf oil is used extensively in the food industry, e.g., for seasoning meat products and soups.

Lavandula products comprise the following oils and extracts:

1) *Lavender oil* is produced by steam distillation of freshly cut, flowering tops of *Lavandula angustifolia* Mill. (Lamiaceae). It is a pale yellow liquid with a fresh, sweet, floral, herbaceous odor on a woody balsamic base. The following physical constants are valid for spontaneous lavender from France.
d_{20}^{20} 0.880 – 0.890; n_D^{20} 1.458 – 1.464; $[\alpha]_D^{20}$ $-11.5°$ to $-7°$; solubility: 1 vol in 2 vol of 75 % ethanol at 20 °C; acid value: max. 1.0; ester value: 102.5 – 165, corresponding to an ester content of 35.8 – 58 % (calculated as linalyl acetate) [273].
True French lavender grows in the Haute Provence at an altitude of 600 – 1500 m. The plants are grown from seeds of the wild lavender ("spontaneous" or "population" lavender). Lavender oil is produced in a yield of 10 – 25 kg/ha; total production is ca. 100 t/a. It has the following typical composition (%): *cis*-β-ocimene (4 – 10), *trans*-β-ocimene (1.5 – 6), cineole (< 1), camphor (< 0.5), linalool (25 – 38), linalyl acetate (25 – 45), 1-terpinen-4-ol (2 – 6), and lavandulyl acetate (> 2).
Cloned varieties of lavender (e.g., *Maillette* and *Matherone*) yield more oil per hectare and can be grown at lower altitudes; however, they produce a poorer quality oil. Bulgarian lavender oil is similar in composition to that obtained from French population lavender, but is of poorer quality: about 50 to 70 t are produced per year.
Lavender oils of a special quality are also produced in several other areas throughout the world (e.g., Tasmania).
2) *Spanish spike lavender oil* is produced by steam distillation of flowering tops of spike, *Lavandula latifolia* Medik. (Lamiaceae). It is an almost colorless to light orange liquid with a characteristic, rough odor slightly like cineole and camphor.
d_{20}^{20} 0.894 – 0.907; n_D^{20} 1.4610 – 1.4680; $[\alpha]_D^{20}$ $-7°$ to $+2°$; solubility: 1 vol in 3 vol of 70 % ethanol; solutions may become opalescent on dilution; acid value: max. 1.0; ester value: 3 – 14; ester value (after acetylation): 130 – 200 [274].
The main components of Spanish spike lavender oil are linalool (34 – 50 %), cineole (16 – 39 %), and camphor (8 – 16 %).
Spike plants grow wild in the entire Mediterranean area and prefer warmer, lower-lying regions than lavender and lavandin. Oil is primarily produced from plants cultivated in Spain. At present, annual worldwide production is ca. 150 – 200 t.
3) *Lavandin oil abrialis* is obtained by steam distillation of freshly cut flowering tops of lavandin, which is a hybrid of lavender and spike (*Lavandula angustifolia* Mill. x *Lavandula latifolia* Medik.). It is a pale yellow liquid with a lavender-like odor and a slightly camphoraceous note.
Data for lavandin oil abrialis: d_{20}^{20} 0.887 – 0.897; n_D^{20} 1.4560 – 1.4660; $[\alpha]_D^{20}$ $-5°$ to $-2°$; solubility: 1 vol in 4 vol of 70 % ethanol at 20 °C; acid value: max. 1.0; ester value: 77 – 108, corresponding to an ester content of 27 – 38 % (calculated as linalyl acetate) [276].
Data for *lavandin oil grosso* (a specific clone of lavandin, cultivated in the South of France: d_{20}^{20} 0.891 – 0.899; n_D^{20} 1.4580 – 1.4620; $[\alpha]_D^{20}$ $-7°$ to $-3.5°$; solubility:

1 vol in 3 vol of 70 % ethanol at 20 °C; acid value: max. 1; ester value: 100 – 137, corresponding to an ester content of 35 – 48 % (calculated as linalyl acetate) [262].

Lavandin plants are sterile and can be propagated only by using cuttings. The oils from the most important varieties, *abrialis* and *grosso,* contain linalool and linalyl acetate as major constituents as well as 6 – 11 % cineole and 7 – 11 % camphor for abrialis, and 4 – 7 % cineole and 6 – 8 % camphor for grosso. A third variety is called *super* because its oil contains a high concentration of linalyl acetate, and, thus, resembles lavender oil most closely.

Although lavender oil is more valuable than lavandin oil as a fragrance raw material, lavandin plants are more commonly cultivated because they give a higher yield of oil (ca. 50 – 100 kg/ha) and are hardier than lavender plants.

Cultivation in southern France is no longer restricted to the traditional lavender regions, but also now includes the Languedoc. Former Yugoslavia is another lavandin-producing country. Worldwide annual production is up to 1100 t.

All three oils are used primarily in soap perfumes; considerable quantities are also employed in eaux de cologne and in bath products.

4) *Lavender and lavandin extracts* are also commercially important and are produced in southern France by solvent extraction of flowering lavender and lavandin herbs. Production of lavandin concrete is higher than that of lavender. Extraction of the pastelike concretes with ethanol, followed by evaporation, yields absolutes. These extracts differ from the essential oils in being more soluble and in having a dark green color and a longer-lasting odor with a haylike, spicy note. They are also used in eaux de cologne and fine fragrances, sometimes after decoloration (removal of chlorophyll with activated charcoal).

Lemon oil, see Citrus Oils, page 94.

Lemongrass oil, see Cymbopogon Oils, page 98.

Lie de vin oil (green cognac oil or wine lees oil) is obtained by steam distillation of the yeast and other sediments (lees) formed in wine. It is a green to bluish-green liquid with a characteristic cognac aroma.

d_{25}^{25} 0.864 – 0.870; n_D^{20} 1.4275 – 1.4295; $[\alpha]_D$ – 1 ° to + 2 °; acid value: 32 – 70; ester value: 200 – 245; solubility: 1 vol in at least 2 vol of 80 % ethanol [277].

Lie de vin oil consists mainly of the ethyl and isoamyl esters of fatty acids, formed during fermentation. It is used mostly in aroma compositions; only very small amounts are employed in perfume compositions.

Lime oil, see Citrus Oils, page 94.

Litsea cubeba oil is produced by steam distillation of the fruits of *Litsea cubeba* C. H. Persoon (Lauraceae) growing in East Asia. It is a pale yellow to dark yellow liquid with a fresh odor, reminiscent of citral.

d_{20}^{20} 0.880 – 0.892; n_D^{20} 1.4800 – 1.4870; $[\alpha]_D^{20}$ + 3 ° to + 12 °; carbonyl content (calculated as citral): min. 74 %; solubility: 1 vol in 3 vol of 70 % ethanol at 20 °C [278].

The oil is used mainly for the production of citral; smaller quantities are employed for perfuming household products. The main producer is China. The worldwide annual production is about 1000 t.

Lovage oils are obtained by steam distillation of either the leaves (leaf oil) or the fresh roots (root oil) of the perennial plant *Levisticum officinale* Koch (Apiaceae). Both oils are yellow-greenish-brown to dark brown liquids with a strong, characteristic, aromatic odor reminiscent of celery and angelica.

d_{25}^{25} 0.960 – 0.985 (leaf oil); d_{20}^{20} 1.010 – 1.090 (root oil); n_D^{20} 1.5350 – 1.5580; $[\alpha]_D^{20}$ – 1 ° to + 5 °; acid value: 2 – 16; ester value: 170 – 260; solubility: 1 vol in 1.5 vol of 85 % ethanol at 20 °C [279].

The main constituent of the leaf oil is α-terpinyl acetate, while the main constituent and odor-determining component of the root oil is ligustilide [*4431-01-0*]. A few percent ligustilide are also present in the leaf oil.

Ligustilide

The oils are very expensive. They are mainly used in the alcoholic beverage industry and for flavoring of tobacco; small amounts are also used in perfumery.

Mace oil, see Nutmeg Oil, page 109.

Mandarin oil, see Citrus Oils, page 94.

Marjoram oil (sweet marjoram oil) is obtained by steam distillation of the herb *Origanum majorana* L. (*Majorana hortensis* Moench, Lamiaceae). The plants are cultivated in France, Hungary, Egypt, and Tunisia. The oil is a yellow to greenish-yellow liquid with a characteristic earthy-spicy odor.

d_{25}^{25} 0.890 – 0.906; n_D^{20} 1.4700 – 1.4750; $[\alpha]_D$ + 14 ° to + 24 °; acid value: max. 2.5; saponification value: 23 – 40; saponification value (after acetylation): 68 – 86; solubility: 1 vol in 2 vol of 80 % ethanol [280].

The main constituent of the oil is 1-terpinen-4-ol (> 20 %), which with (+)-*cis*-sabinene hydrate [*15537-55-0*] (3 – 18 %) is responsible for the characteristic flavor and fragrance of marjoram oil.

(+)-*cis*-Sabinene hydrate

Sweet marjoram oil is used mainly for flavoring foods, but also in smaller amounts in perfumery for spicy shadings in men's fragrances.

Spanish marjoram oil is obtained by steam distillation of the flowering tops of *Thymus mastichina* L. (Lamiaceae), a wild plant growing in Spain. The oil is a slightly yellow liquid with a fresh camphoraceous, spicy odor.

d_{20}^{20} 0.890 – 0.920; n_D^{20} 1.460 – 1.470; $[\alpha]_D^{20}$ − 4 to + 6 °; 1,8-cineole content: min. 30 %, max. 68 %; solubility: 1 vol in 3 vol of 70 % ethanol [281].

Mentha citrata oil, see Mint Oils.

Mimosa absolute is obtained from the blossoms of the mimosa tree *Acacia dealbata* Link (Mimosaceae), which grows in the forests of southern France and in Morocco.

The absolute is a yellowish brown liquid with a slightly green, flowery odor and extremely high tenacity.

Annual production in France (Grasse) is ca. 3 – 6 t [282]. Mimosa absolute is used mainly in fine fragrances as a flowery fixative.

Mint oils are listed in order of the quantities produced.

1) *Cornmint oil* is produced by steam distillation of the flowering herb *Mentha arvensis* L. var. *piperascens* Malinv. and var. *glabrata* Holmes (Lamiaceae). The crude oil, containing ca. 70 % (−)-menthol, is then partially dementholized by freezing and centrifuging. The dementholized oil is an almost colorless to amber-yellow liquid with a characteristic minty odor; typical specifications for oils of Chinese and Indian origin are as follows:
   d_{20}^{20} 0.890 – 0.910; n_D^{20} 1.4570 – 1.4650; $[\alpha]_D^{20}$ − 24 ° to − 13 °; ester content (calculated as menthyl acetate): 3 – 9 %; total alcohol content (calculated as menthol): 40 – 60 %; ketone content (calculated as menthone): 25 – 45 %; solubility: 1 vol in 4 vol of 70 % ethanol [283].
   Dementholized oil still contains ca. 45 % (−)-menthol; (−)-menthone and (−)-menthyl acetate are other major components. Dementholized *Mentha arvensis* oil was formerly produced primarily in Brazil. Currently, cornmint oil is produced mainly in China; smaller amounts are produced in India and Paraguay. The world production of the oil is estimated to be 17 000 to 18 000 t/a. Dementholized cornmint oil tastes more bitter and stringent than peppermint oil. Thus, the former is used as a cheaper substitute for the latter and for the production of (−)-menthol (see page 30).
2) *Peppermint oil* is produced by steam distillation of the aerial plant *Mentha* x *piperita* L. var. *piperita*. It is an almost colorless to pale

greenish-yellow liquid with a characteristic peppermint odor.
d_{20}^{20} 0.898 – 0.918; n_D^{20} 1.4590 – 1.4650; $[\alpha]_D^{20}$ – 30° to – 14°; solubility: 1 vol in 5 vol of 70 % ethanol at 20 °C; ester value: 12 – 30; ester value (after acetylation): 135 – 200; carbonyl value: 54 – 115 [284].
As in cornmint oil, the main component of peppermint oil is (–)-menthol; it also contains (–)-menthone (ca. 20 %) and (–)-menthyl acetate (up to 8 %). However, peppermint oil, unlike cornmint oil, has a high content of (+)-menthofuran [*17957-94-7*] (1 – 8 %, according to GLC).

(+)-Menthofuran

The leading producer of peppermint oil is the United States, where annual production from the variety *M. piperita* L. var. *vulgaris* Sole (Black Mitcham) is ca. 3600 t. Cultivation areas are located in the Midwest states, Idaho, Oregon, and Washington. The oils differ in quality and are named according to their geographic origin (e.g., Midwest, Idaho, Madras, Willamette, Yakima). Production of European oil has decreased significantly, despite its high quality. Peppermint oil is used mainly for flavoring toothpaste, other oral hygiene products, and chewing gum. Smaller quantities are used for flavoring confectioneries. Due to its high price, peppermint oil is not used for the production of menthol.

3) *Spearmint oil* is obtained by steam distillation of the flowering tops of *Mentha spicata* L. (native spearmint) and *Mentha* x *cardiaca* Ger. (Scotch spearmint). It is an almost colorless to yellow-green liquid with a fresh, caraway-minty odor.
d_{20}^{20} 0.920 – 0.937; n_D^{20} 1.485 – 1.491; $[\alpha]_D^{20}$ – 60° to – 45°; solubility: 1 vol in 1 vol of 80 % ethanol at 20 °C; carbonyl value: min. 200, corresponding to a carvone content of 55 % [285].
The compositions of Scotch and native spearmint oils differ as shown in Table 4 [286]. The main producer of spearmint oil is the United States, primarily the state of Washington. Smaller amounts are also produced in some Midwest states. Total annual production is ca. 1750 t, 55 % being of the native type and 45 % of the Scotch type.

Table 4. Characteristic components of Scotch and native spearmint oils

Compound	Content of compound in spearmint oil, %	
	Scotch	Native
Limonene	15	9
3-Octanol	2	1
Menthone	1	< 0.1
Dihydrocarvone	1	2.5
Sabinene hydrate	0.1	1.5
Dihydrocarvyl acetate	< 0.1	0.6
cis-Carvyl acetate	0.1	0.6

By far the most spearmint oil is used for flavoring toothpaste and chewing gum. Smaller quantities are used in other oral hygiene products and in pharmaceutical preparations.

4) *Mentha citrata oil* is distilled from the herb *Mentha citrata* Ehrh. It has a lavender-like odor and contains linalool and linalyl acetate as major components (together ca. 70 %). Recently, hybrids of the plant have been developed in the United States and other countries that yield oils with a total linalool content of over 80 % [287]. Currently, the main cultivation area is Eastern Asia. *Mentha citrata* oils are used mainly for perfuming soap and cosmetics.

5) *Pennyroyal oil* is obtained by steam distillation of the flowering tops of *Mentha pulegium* L. It is an almost colorless to amber-yellow liquid with a herbaceous, minty odor.
d_{20}^{20} 0.930 – 0.944; n_D^{20} 1.4800 – 1.4900; $[\alpha]_D^{20}$ + 15° to + 24°; solubility: 1 vol in 3 vol of 70 % ethanol; content of carbonyl compounds (calculated as pulegone) min. 80 % [288].
The main component of pennyroyal oil is (+)-pulegone [*89-82-7*] (ca. 80 %). About 50 t of the oil are produced per year, mainly in southern Spain and Tunisia.

(+)-Pulegone

An oil of similar composition, also called pennyroyal oil, is obtained in North America from *Hedeoma pulegioides* L. Pennyroyal oil has lost its significance as a starting material for the production of (−)-menthol. However, it is still used in perfume compositions for soap and oral hygiene products.

Musk, see Animal Secretions, page 87.

Myrrh oil and myrrh resinoids are produced from the air-dried gum of *Commiphora myrrha* (Nees) Engl. var. *molmol* Engl., *C. abyssinica* (Berg) Engl. and *C. schimperi* (Berg) Engl. (Burseraceae), shrubs that grow in Northeast Africa and Arabia.

Myrrh resinoids are obtained in 20 – 45 % yield by extracting the gum with suitable solvents (e.g., benzene, hexane). They are waxlike, brown-yellow to red-brown masses with a balsamic odor and an aromatic bitter taste.

Acid value: 20 – 35; ester value: 165 – 200; carbonyl value: 20 – 75 [289].

Myrrh oil is obtained from the gum by steam distillation; it is a light brown or green liquid with the characteristic odor of the gum.

d_{25}^{25} 0.995 – 1.014; n_D^{20} 1.5190 – 1.5275; $[\alpha]_D$ − 83 ° to − 60 °; acid value: 2 – 13; saponification value: 9 – 35; solubility: 1 vol in 7 – 10 vol of 90 % ethanol; solutions are occasionally opalescent or turbid [290].

Typical aroma-determining compounds of the myrrh plant are furanosesquiterpenoids such as lindestrene [*2221-88-7*] [291].

Lindestrene

Neroli oil and orange flower absolute are obtained from the blossoms of the bitter orange tree, *Citrus aurantium* L. subsp. *aurantium,* syn. *Citrus aurantium* L. subsp. *amara var. pumilia*, (Rutaceae), which is grown in France, Italy, and North Africa. *Neroli oil* is produced by steam distillation (about 4 t/a) and is a pale yellow to amber-colored liquid, with a slight blue fluorescence and a characteristic sweet, spicy-bitter odor of orange blossom.

d_{20}^{20} 0.864 – 0.876; n_D^{20} 1.460 – 1.474; $[\alpha]_D^{20}$ + 2 ° to + 11 °; solubility: 1 vol in 3.5 vol of 85 % ethanol at 20 °C; acid value: max. 2.0; ester value: 26 – 60 [292].

After separation of neroli oil, the aqueous layer of the steam distillate, known as orange blossom water, is extracted with suitable solvents (e.g., petroleum ether). Evaporation gives *orange flower water absolute* (absolue de l'eau de fleurs d'oranger), which is a dark brown-red liquid. It contains less terpene hydrocarbons and correspondingly more polar compounds than neroli oil.

Orange flower absolute is obtained from the blossoms by solvent extraction via the concrete. It is a dark brown liquid with a warm, spicy-bitter odor.

The main volatile constituent of all three products is linalool. Their typical flavor is created by a number of nitrogen-containing trace constituents, such as indole and derivatives of anthranilic acid.

Neroli oil and the related products are some of the most expensive natural raw materials and are produced only in small quantities (a few tons per year). They are used in fine fragrances; neroli oil, for example, is one of the classical components of eaux de cologne.

Nutmeg (mace) oil is obtained by steam distillation of the dried and crushed nuts and/or the coverings (mace) of nutmeg, which are the fruits of *Myristica fragrans* Houtt. (Myristicaceae). The tree grows in Indonesia and in the West Indies and becomes 15 – 20 m high. Nutmeg oil is a colorless to pale yellow liquid with a pleasant spicy odor. Its physical constants and odor vary with the place of origin. Specifications of Indonesian and (in parentheses) West Indian nutmeg oil are as follows:

d_{20}^{20} 0.885 – 0.907 (0.862 – 0.882); n_D^{20} 1.4750 – 1.4850 (1.4720 – 1.4760); $[\alpha]_D^{20}$ + 6 ° to + 18 ° (+ 25 ° to + 40 °); solubility (both oils): 1 vol in 5 vol of 90 % ethanol at 20 °C (solutions

sometimes opalescent), for freshly distilled oils, 1 vol in 3 – 4 vol [293].

Indonesian oils contain a higher percentage of higher boiling components than do West Indian oils (produced mainly in Grenada).

The oils contain ca. 90 % terpene hydrocarbons, mainly sabinene and α- and β-pinene. Major oxygen-containing constituents are 1-terpinen-4-ol and phenol ether derivatives (mainly myristicin).

Nutmeg oil is used mainly in food flavorings and to a lesser extent in perfumery. Worldwide annual production is 400 to 450 t, more than 120 t/a is produced in Indonesia alone.

Oakmoss absolute and tree moss absolute are obtained from tree lichens. *Oakmoss absolute* is derived from *Evernia prunastri* (L.) Arch. (Usneaceae), a lichen growing on oak trees. The lichen is first extracted with nonpolar solvents to give a concrete. The waxes are then removed by precipitation with ethanol, leaving an absolute.

The concretes are green to brown waxy pastes; the absolutes are more or less viscous liquids with an earthy, mossy, woody odor and a slight phenolic, leather note.

Resorcinol derivatives, e.g., orcinol [*504-15-4*], β-orcinol [*488-87-9*], their monomethyl ethers, and methyl 3-methylorsellinate [*4707-47-5*] are mainly responsible for the characteristic earthy-moss-like odor of the oakmoss products.

Tree moss concretes and absolutes are prepared from *Pseudevernia furfuracea*, a lichen growing on conifer bark. Their odors are different from those of the corresponding oakmoss products.

Orcinol

β-Orcinol

Methyl 3-methylorsellinate

Large quantities of oakmoss (mousse de chêne) and tree moss (mousse d'arbre) are collected annually in former Yugoslavia, France, and Morocco [294]. In 1997 1900 t of Pseudevernia furfuracea and 700 t of Evernia prunastri were processed, mainly in Grasse [295].

The extracts and absolutes are used in perfumery for nuances and as a fixative to give compositions a dry, sweet base note, e.g, in fougère and chypre perfumes. (IFRA recommendation).

Olibanum oil and olibanum resinoid are obtained from frankincense, which is a gum resin collected from the bark of the tree *Boswellia carteri* Birdw. (syn. *B. sacra* Flueck.) or *B. frereana* Birdw. (Burseraceae) growing in Yemen and Somalia. The resinoid is produced by solvent extraction, and steam distillation gives the oil, which is a pale yellow, slightly viscous liquid with a balsamic odor and a faint lemon note.

d_{25}^{25} 0.862 – 0.889; n_D^{20} 1.4650 – 1.4820; $[\alpha]_D$ $-15°$ to $+35°$; solubility: 1 vol in 6 vol of 90 % ethanol, solutions occasionally opalescent; acid value: max. 4.0; ester value: 4 – 40 [296].

Various qualities are commercially available. Their compositions may vary considerably because they are prepared from the resins of different *Boswellia* species [297].

Olibanum oil and resinoid are used in oriental type perfumes for their odor and their good fixative properties.

Opopanax oil and opopanax resinoid (also: Opoponax) are obtained from the resin of *Commiphora erythraea* Engl. var. *glabrescens* Engl., a tree growing in Somalia (Burseraceae). The resinoid is prepared by solvent extraction, and steam distillation of the resin gives the essential oil, which is a yellow to greenish-yellow liquid with a warm, sweet, balsamic odor.

d_{25}^{25} 0.865 – 0.932; n_D^{20} 1.488 – 1.504; $[\alpha]_D$ $-32°$ to $-9°$; acid value: max. 4; saponification value: 4 – 20; solubility: 1 vol in 10 vol of 90 % ethanol; solutions are occasionally turbid [298].

Opopanax oil and resinoid are used in perfume compositions with oriental characteristics. (IFRA recommendation).

Orange flower absolute, see Neroli Oil, page 109.

Orange oils, see Citrus Oils, page 94.

Origanum oils are produced from several species of the flowering herb *Origanum* (Lamiaceae). Spanish origanum oil is derived from *Coridothymus capitatus* Rchb. and is often called white thyme oil. The oils differ mainly in their content of carvacrol and thymol, which are major constituents. Oil with a high carvacrol content [*499-75-2*] (for formula, see page 116) is a yellowish-red to dark brown liquid with a spicy, herbaceous odor, reminiscent of thyme. The color quickly turns to black when in contact with iron.

d_{25}^{25} 0.935 – 0.960; n_D^{20} 1.5020 – 1.5080; $[\alpha]_D$ – 2 ° to + 3 °; phenol content: 60 – 75 %; solubility: 1 vol in 2 vol of 70 % ethanol; solutions may become turbid when further diluted [299].

According to ISO the Spanish origanum oil is derived from *Thymbra capitata* (L.) Cav. It is a yellowish to dark brown, almost black oil with an aromatic, phenolic, and spicy odor; d_{20}^{20} 0.930 – 0.955; n_D^{20}1.5000 – 1.5130; $[\alpha]_D^{20}$ – 5 ° to + 2 °; solubility: 1 vol in 4 vol of 70 % ethanol at 20 °C; carvacrol content by GLC: 60 to 75 % [300]. (Both botanical names – *Coridothymus* and *Thymbra* – are not mentioned in the Zander dictionary [196].)

Origanum oils are used in perfume compositions and in seasoning mixtures.

Orris root oil is obtained by steam distillation of the rhizomes of the two species of iris, *Iris pallida* Lam. or *Iris germancia* L. (Iridaceae). Prior to distillation the rhizomes are stored for about two years in order to develop the aroma and are then ground. The steam distillate is a light yellow to brown-yellow solid mass with a violet-like odor. The solid liquefies to a yellow to yellow-brown liquid at 38 – 50 °C.

Acid value: 175 – 235, corresponding to an acid content of 71 – 95 % (calculated as myristic acid); ester value: 4 – 35; ketone content (calculated as irone): 9 – 20 %; soluble with ethanol in all proportions at 50 °C [301].

Because of its high content of myristic and other fatty acids, the steam distillate is a waxy mass that resembles a concrete and is sold under this name or as *Beurre d'Iris* (Orris butter). In addition, a neutral product, obtained after removal of the acids with alkali, is marketed under the name *orris oil absolute* or as *orris oil 10-fold.*

The main constituents of the oil are (–)-*cis*-γ-irone [*89888-04-0*] and (–)-*cis*-α-irone [*89888-03-9*], which are responsible for its odor [302].

(–)-*cis*-γ-Irone

(–)-*cis*-α-Irone

The oil, respectively the butter, is very expensive and is used in perfumery and in flavor compositions.

Palmarosa oil, see Cymbopogon Oils, page 98.

Parsley oils are produced from the plant *Petroselinum crispum* (Mill.) Nyman. ex A.W. Hill (P. *sativum* Hoffm.), (Apiaceae):

1) *Parsley leaf oil* is produced by steam distillation of the aerial parts of the plant, including the immature seeds. It is a yellow to light-brown liquid with the typical odor of the herb. d_{25}^{25} 0.908 – 0.940; n_D^{20} 1.5030 – 1.5300; $[\alpha]_D$ – 9 ° to + 1 °; acid value: max. 2; soluble in 95 % ethanol; solutions may be opalescent [303].
   The oil consists mainly of monoterpene hydrocarbons. Its main constituent is 1,3,8-menthatriene [*18368-95-1*], which – together with two pyrazines and (*Z*)-dec-6-enal – is important for the aroma of parsley leaves [304].
2) *Parsley seed oil* is obtained by steam distillation of ripe fruits of parsley. It is an almost colorless to amber-yellow liquid whose dry odor is characteristic of the crushed fruit, but different from that of the green parts of the plant.
   d_{20}^{20} 1.043 – 1.083; n_D^{20} 1.5130 – 1.5220; $[\alpha]_D^{20}$ – 10 ° to – 4 °; acid value: max. 6; ester value: min. 1, max. 10; solubility: 1 vol in 6 vol of 85 % ethanol, solutions are sometimes slightly turbid [306].
   Characteristic components of parsley seed oil are myristicin [*607-91-0*], apiol [*523-80-8*], and 2,3,4,5-tetramethoxyallylbenzene [*15361-99-6*] [305].

Myristicin

Apiol

2,3,4,5-Tetramethoxyallylbenzene

Parsley oils are used in the food industry in seasonings, for example, for meat and sauces.

Patchouli oil is produced by steam distillation of the dried leaves of *Pogostemon cablin* (Blanco) Benth. (Lamiaceae). It is a yellow to reddish-brown, more or less viscous liquid with a characteristic, slightly camphoraceous, woody balsamic odor.

d_{20}^{20} 0.952 – 0.975; n_D^{20} 1.5050 – 1.5150; $[\alpha]_D^{20}$ – 60 ° to – 40 ° (in exceptional cases to – 32 °); solubility: 1 vol in 10 vol of 90 % ethanol at 20 °C; acid value: max. 4.0; ester value: max. 10 [307].

The patchouli shrub is cultivated primarily in Indonesia. It grows to 1 m, but during harvesting is cut back to 10 – 15 cm. The oil yield from preferably sun-dried leaves is ca. 2 %.

Although the sesquiterpene alcohol (–)-patchoulol [*5986-55-0*] is the main component of patchouli oil (27 – 35 %), this compound contributes less to the characteristic odor of the oil than norpatchoulenol [*41429-52-1*] present only at a concentration of 0.2 – 1 % [308].

Patchoulol

Norpatchoulenol

Worldwide production lies between 900 and 1000 t/a. Patchouli oil is very tenacious and is used in perfumery for oriental and fougère notes.

Pennyroyal oil, see Mint Oils, page 107.

Pepper oil and pepper oleoresin are obtained from the black pepper *Piper nigrum* L. (Piperaceae). Pepper oil is produced by steam distillation of whole or broken unripe fruits. The oil is an almost colorless to bluish-green liquid with a characteristic odor, reminiscent of pepper, but without the pungency of the spice.

d_{20}^{20} 0.870 – 0.890; n_D^{20} 1.480 – 1.492; $[\alpha]_D^{20}$ – 16 ° to + 4 °; solubility: 1 vol in 3 vol of 95 % ethanol; ester value: max. 11 [309].

The oil contains mainly monoterpene hydrocarbons (ca. 80 %), its main constituent being sabinene [*3387-41-5*] (20 – 25 %).

Sabinene

Pepper oleoresin is produced by solvent extraction and, unlike the oil, contains the principal pungent compound, piperine [*94-62-2*], along with some essential oil.

Piperine

Pepper products are used for flavoring foods; pepper oil is also employed to a small extent in perfume compositions.

Peppermint oil, see Mint Oils, page 107.

Peru balsam oil is obtained by distillation of the balsam of *Myroxylon pereirae* (Royle) Klotzsch (Fabaceae). It is a yellow to pale brown, slightly viscous liquid, which may form crystals with a rather sweet, balsamic odor.

d_{25}^{25} 1.095 – 1.110; n_D^{20} 1.5670 – 1.5790; $[\alpha]_D$ – 1 ° to + 2 °; acid value: 30 – 60; ester value: 200 – 225; solubility: 1 vol in at least 0.5 vol of 90 % ethanol [310].

Peru balsam is produced almost exclusively in El Salvador. The oil yield from the balsam is ca. 50 %. Major components are benzyl benzoate and benzyl cinnamate. Nerolidol and vanillin contribute to the odor.

The oil is used for its excellent fixative properties in perfumes for soap and cosmetics. Use of Peru balsam itself is now banned because it is allergenic. (IFRA recommendation)

Petitgrain oils are obtained by steam distillation of the leaves of citrus trees (Rutaceae family). The oils derived from the bitter orange tree are the most important. Other petitgrain oils (mandarinier, citronnier, and bergamotier) are less important. Petitgrain oil mandarinier is a source of natural methyl *N*-methylanthranilate, which is present at a concentration of more than 50 %. Petitgrain oils are essential constituents of eaux de cologne.

Petitgrain oil Paraguay is obtained from an acclimatized variety of the bitter orange tree, *Citrus aurantium* L. subsp. *aurantium,* which is grown in Paraguay. Leaves and twigs are steam distilled. Petitgrain oil Paraguay is a colorless to pale yellow liquid with a characteristic, strong, pleasant odor, reminiscent of linalool and linalyl acetate.

d_{20}^{20} 0.882 – 0.893; n_D^{20} 1.455 – 1.463; $[\alpha]_D^{20}$ $-6°$ to $-1°$; solubility: 1 vol in 4 vol of 70 % ethanol at 20 °C; acid value: max. 1; ester value: 127 – 184, corresponding to an ester content of 45 – 65 % (calculated as linalyl acetate) [311].

Annual production is ca. 250 – 280 t.

Petitgrain oil bigarade is obtained by steam distillation of the leaves, twigs, and small green fruits of the bitter orange tree *Citrus aurantium* L. subsp. *aurantium,* grown in France, Italy, and North Africa. It is a pale yellow to amber yellow liquid, with a slight blue fluorescence and with a characteristic ethereal and pleasant odor.

d_{20}^{20} 0.886 – 0.898; n_D^{20} 1.4560 – 1.4720; $[\alpha]_D^{20}$ $-6°$ to $+1°$; solubility: 1 vol in 5 vol of 70 % ethanol at 20 °C; acid value: max. 2; ester value: 140 – 217, corresponding to an ester content of 50 – 77 % (calculated as linalyl acetate) [312].

Annual production is ca. 3 to 5 t.

Pimento oils (allspice oil) are derived from pimento fruits and leaves. Pimento berry oil is obtained by steam distillation of the dried, fully grown, unripe, berry-like fruits of the pimento shrub, *Pimenta dioica* (L.) Merrill. (Myrtaceae), growing in Jamaica. It is a pale yellow to brown liquid with a spicy odor, reminiscent of eugenol.

d_{20}^{20} 1.027 – 1.048; n_D^{20} 1.5250 – 1.5400; $[\alpha]_D^{20}$ $-5°$ to $0°$; solubility: 1 vol in 2 vol of 70 % ethanol at 20 °C; phenol content: min. 65 % [313].

The major components of pimento berry oil are eugenol (up to 75 %), 1,8-cineole, and caryophyllene. Distillation of the leaves gives an oil that has an even higher content of eugenol (80 – 90 %). Annual production of leaf oil is ca. 50 t, which exceeds that of the berry oil.

Pimento oils, like the spice itself, are used mainly in the food industry, as well as in perfume compositions for creating spicy, clovelike notes.

Pinaceae needle oils from Pinaceae species contain (−)-bornyl acetate as their main odoriferous component. Other main constituents are monoterpene hydrocarbons such as α- and β-pinene, limonene, 3-carene, and α- and β-phellandrene. The oils are used in perfumes for soap, bath products, and air fresheners and in pharmaceutical preparations.

1) *European silver fir oil* is produced in central Europe by steam distillation of needle-bearing twigs of *Abies alba* Mill. It is a colorless to pale yellow liquid with a pleasant odor of freshly cut fir needles.
   d_{25}^{25} 0.867 – 0.878; n_D^{20} 1.4700 – 1.4750; $[\alpha]_D$ $-67°$ to $-34°$; solubility: 1 vol in 7 vol of 90 % ethanol; ester content (calculated as bornyl acetate): 4 – 10 % [314].
   Silver fir cone oil (templin oil) obtained from the cones of *Abies alba* Mill. has similar properties.
2) *Siberian fir needle oil* is obtained by steam distillation of needles and twigs of *Abies sibirica* Ledeb., the Siberian silver fir. It is an almost colorless or pale yellow liquid with a characteristic fir odor.
   d^{25} 0.898 – 0.912; n_D^{20} 1.4685 – 1.4730; $[\alpha]_D$ $-45°$ to $-33°$; solubility: 1 vol in 1 vol of 90 % ethanol, solutions may become hazy when further diluted; ester content (calculated as bornyl acetate): 32 – 44 % [315].
3) *Canadian fir needle oil* (balsam fir oil) is produced in Canada and in several northern states of the United States from needles and twigs of *Abies balsamea* (L.) Mill. It is an almost colorless to pale yellow liquid with a pleasant balsamic odor.
   d_{25}^{25} 0.872 – 0.878; n_D^{20} 1.4730 – 1.4760; $[\alpha]_D$ $-24°$ to $-19°$; solubility: 1 vol in 4 vol of 90 % ethanol (turbidity may occur), ester content (calculated as bornyl acetate): 8 – 16 % [316].
4) *Pine needle oil* is produced primarily in Austria (Tyrol), former Yugoslavia, and the CIS by steam distillation of the needles of the

Norwegian or Scotch pine, *Pinus sylvestris* L. It is a colorless or yellowish liquid with an aromatic, turpentine-like odor.
d_{25}^{25} 0.857 – 0.885; n_D^{20} 1.4730 – 1.4785; $[\alpha]_D$ $-4°$ to $+10°$; solubility: 1 vol in 6 vol of 90 % ethanol, sometimes slightly opalescent; ester content (calculated as bornyl acetate): 1.5 – 5 % [317].

5) *Dwarf pine needle oil* is obtained in Austria (Tyrol) and other mountainous areas of central and southeast Europe by steam distillation of fresh needles and twig tips of *Pinus mugo* Turra subsp. *mugo* Zenari and subsp. *pumilio* (Haenke) Franco. It is a colorless liquid with a pleasant, balsamic odor.
d_{25}^{25} 0.853 – 0.871; n_D^{20} 1.475 – 1.480; $[\alpha]_D^{25}$ $-16°$ to $-3°$; solubility: 1 vol in 10 vol of 90 % ethanol; bornyl acetate content is similar to that of pine needle oil.
6) *Spruce and hemlock oils* are produced in Canada and the Northeast of the United States by steam distillation of needles and twigs from *Picea mariana* (Mill.) B.S.P. (black spruce), *Picea glauca* (Moench) Voss (white spruce), *Tsuga canadensis* (L.) Carrière (Eastern Hemlock), and related species. They are very pale to light yellow liquids with a pleasant odor reminiscent of pine needles.
d_{25}^{25} 0.900 – 0.915; n_D^{20} 1.4670 – 1.4720; $[\alpha]_D$ $-25°$ to $-10°$; solubility: 1 vol in at least 1 vol of 90 % ethanol; solutions may become hazy when > 2 vol of 90 % ethanol are added; ester content (calculated as bornyl acetate): 37 – 45 % [318].

Rose oil and rose absolute are used mainly in fine fragrances. Rose oil is also used in small amounts for flavoring purposes.

1) *Rose oil* is obtained by steam distillation of blossoms of *Rosa* x *damascena* Mill. (Rosaceae) that is mainly cultivated in Turkey, Bulgaria (Kazanlik rose), and Morocco. Since a reasonable amount of rose oil is still dissolved in the aqueous phase after steam distillation, the distillation water (*rose water*) is redistilled or extracted.
Rose oil is a yellow to greenish-yellow liquid with the characteristic odor of rose blossoms and distinct tea and honey notes.
d_{20}^{20} 0.848 – 0.880; n_D^{25} 1.4520 – 1.4700; $[\alpha]_D^{20}$ $-5°$ to $-1.8°$; *fp* between 16 and 23.5 °C; ester value: min. 7, max. 24. Due to the presence of paraffin hydrocarbons (stearoptenes) the determination of the physical constants at 20 °C can be difficult or impossible because of a low freezing-point [319].
The major constituents of rose oil are (−)-citronellol, geraniol, and nerol. In contrast to the absolute (see below), the oil contains only a minor amount of phenethyl alcohol, which is extremely soluble in water.
In addition to the major components mentioned above, Bulgarian rose oil also contains a number of components which, although present in low concentrations, contribute to the characteristic fragrance. Among these are β-damascenone (see page 39) and rose oxide (see page 72) [320].
Since ca. 3 t of blossoms are required to prepare ca. 1 kg of oil, rose oil is one of the most expensive essential oils. Production is limited and is only about 30 t per year.
2) *Rose absolute* is prepared from the concrete extracted from *Rosa* x *damascena* in the countries mentioned above, as well as from *Rosa centifolia* L. (rose de mai) in Morocco and the south of France.
The absolute is a reddish liquid with a typical rose odor. The phenethyl alcohol content of its volatile fraction is 60 – 75 % [321].

Rosemary oil is obtained by steam distillation of the twigs and flowering tops of *Rosmarinus officinalis* L. (Lamiaceae). It is an almost colorless to pale yellow or yellow-greenish liquid with a characteristic, refreshing, pleasant odor.

For oils type *Spain*: d_{20}^{20} 0.892 – 0.910; n_D^{20} 1.4640 – 1.4760; $[\alpha]_D^{20}$ $-5°$ to $+8°$; ester content (calculated as bornyl acetate): 2 – 5 %; acid value: 1.0; solubility: 1 vol in 3 vol of 90 % ethanol.

For oils type *Tunisia and Morocco*: d_{20}^{20} 0.907 – 0.920; n_D^{20} 1.4640 – 1.470; $[\alpha]_D^{20}$ $-2°$ to $+5°$; ester content (calculated as bornyl acetate): 2 – 5 %; acid value: 1.0; solubility: 1 vol in 2 vol of 80 % ethanol [322]

Major components are 1,8-cineole, α-pinene, and camphor, which comprise up to 55 %, 30 % and 22 %, respectively of commercial oils. The

composition of the oil varies with its origin. North African oils (e.g., from Tunisia) are comparatively high in cineole. Spanish oils have a lower cineole content, but a higher camphor (up to 22 %) and monoterpene hydrocarbon content (30 – 40 %). Verbenone [*18309-32-5*] is also important for the odor; it may occur in traces or as a major component; its content in the Spanish oils is higher than in the North African ones [323].

Verbone

The main producers of rosemary oil are in Tunisia and Spain. About 100 to 150 t are produced annually. Rosemary is used widely in perfumery and in large amounts for perfuming bath foams, shampoos, and hair tonics.

Rosewood oil, Brazilian (Bois de rose oil) is obtained by steam distillation of wood from *Aniba rosaeodora* Ducke var. *amazonica* Ducke and/or *A. parviflora* (Meissner) Mez (Lauraceae). It is an almost colorless to pale yellow liquid with a characteristic, sweet odor, reminiscent of linalool.

d_{20}^{20} 0.870 – 0.887; n_D^{20} 1.4620 – 1.4690; $[\alpha]_D^{20}$ $-2°50'$ to $+4°$; solubility: 1 vol in 9 vol of 60 % ethanol at 20 °C; acid value: max. 1; ester value: max. 5; ester value (after acetylation): 247 – 280, corresponding to an alcohol content of 82 – 96 % (calculated as linalool) [324].

Brazilian rosewood oil is no longer competitive as a raw material for linalool. Increasing production costs, as well as the development of large-scale processes for fully synthetic linalool (for production of vitamin A), have led to a sharp decline in production (annual production ca. 20 – 30 t). Currently, rosewood oil is only used in small amounts in perfumes, e.g., for soaps.

Sage oils are of three main types:

1) *Clary sage oil* is obtained by steam distillation of flowering tops and foliage of cultivated *Salvia sclarea* L. (Lamiaceae). The quality *Broyée en vert* is obtained after cutting the fresh material and immediate distillation. Another quality named *Traditionelle* exists, which is obtained by steam distillation after drying of the tops and foliage on the field. Both qualities are pale yellow to yellow liquids with a herbaceous odor and a winelike bouquet.
Physical constants for the quality *Broyée en vert*: d_{20}^{20} 0.890 – 0.902; n_D^{20} 1.4560 – 1.4660; $[\alpha]_D^{20}$ $-20°$ to $-10°$; solubility: 1 vol in 3 vol of 80 % ethanol; solutions become opalescent on dilution; acid value: max. 1; ester content (calculated as linalyl acetate): 63 – 75 % [325].
In addition to linalyl acetate, the oil contains linalool and other terpene alcohols, as well as their acetates. When the volatile components are evaporated, a distinct ambergris note develops that is attributed to oxidative degradation products of sclareol [*515-03-7*]. Sclareol is the main component in the concrete, obtained by solvent extraction of *S. sclarea* L. leaves.

Sclareol

Sclareol is used as a starting material for a number of ambergris fragrances. Major cultivation areas for *S. sclarea* L. are the CIS, the Mediterranean and Balkan countries, and more recently the United States. The annual production is between 50 and 150 t.
Clary sage oil is used extensively in fine fragrances.

2) *Dalmatian sage oil* is obtained by steam distillation of the partially dried leaves of *Salvia officinalis* L. (Lamiaceae). It is a colorless to yellow liquid with a warm camphoraceous, thujone-like odor and sharp and bitter taste.
d_{20}^{20} 0.910 – 0.930; n_D^{20} 1.4580 – 1.4740; $[\alpha]_D$ $+2°$ to $+30°$; saponification value: 6 – 20; ketone content (calculated as thujone): 28 – 78 %; solubility: 1 vol in 2 vol of 80 % ethanol at 20 °C [326].
The major components of *S. officinalis* oil are camphor and α-thujone [*546-80-5*]. β-

thujone [*471-15-8*] is present in ca. 5 % concentration.

α-Thujone [(−)-thujone]

β-Thujone [(+)-isothujone]

The oil is used in pharmaceutical preparations and in perfumery to create dry, spicy-herbaceous notes.

3) *Spanish sage oil* is produced by steam distillation of leaves and twigs of *Salvia lavandulifolia* Vahl (Lamiaceae) growing in Spain in the provinces Granada, Murcia, Almeria, and Jaén. The oil is an almost colorless to pale yellow liquid with the characteristic camphoraceous odor of the leaves.
d_{20}^{20} 0.907 – 0.930; n_D^{20} 1.465 – 1.472; $[\alpha]_D^{20}$ − 12 ° to + 17 °; solubility: 1 vol in 2 vol of 80 % ethanol at 20 °C; acid value: max. 2.0; ester value: min. 15, max. 55 [327].
Unlike Dalmatian sage oil, Spanish sage oil contains no or only traces of α- or β-thujone; camphor and 1,8-cineole are the major components and are responsible for the odor of the oil, which is used primarily in pharmaceutical preparations.
Altogether about 50 t of Spanish and Dalmatian oils are produced annually.

Sandalwood oil, East Indian is obtained by steam distillation of the heartwood of *Santalum album* L. (Santalaceae). It is a slightly viscous, almost colorless to golden yellow liquid with a characteristic, sweet, woody, long-lasting odor.

d_{20}^{20} 0.968 – 0.983; n_D^{20} 1.5030 – 1.5080; $[\alpha]_D^{20}$ − 21 ° to − 12 °; solubility: 1 vol in 5 vol of 70 % ethanol at 20 °C; ester value: min. 10; free alcohol content (calculated as santalol): min. 90 %.

East Indian sandalwood oil consists almost exclusively of closely related sesquiterpenoids; the alcohols *cis*-α-santalol [*115-71-9*] (45 – 55 %) and *cis*-β-santalol [*77-42-9*] (18 – 24 %) are mainly responsible for its odor [328].

α-Santalol

β-Santalol

The trees cultivated for oil production must be at least 30 years old to make oil production profitable. The oil yield, calculated on the amount of wood used for steam distillation, is 4 – 6.5 %. Indian production is ca. 60 t/a. Smaller quantities are produced in neighboring countries.

East Indian sandalwood oils are used extensively in perfumery as very valuable, stable fixatives.

Sassafras oil, Brazilian is obtained by steam distillation of the roots, trunks, and branches of *Ocotea pretiosa* (Nees) Mez (Lauraceae). The oil was formerly called *Ocotea cymbarum* oil due to incorrect botanical naming. It is a yellow to brownish liquid with the characteristic odor of safrole.

d_{20}^{20} 1.082 – 1.094; n_D^{20} 1.5330 – 1.5370; $[\alpha]_D^{20}$ − 0.5 ° to + 3.0 °; solubility: 1 vol in 2 vol of 90 % ethanol; *fp* + 7.5 to + 9.5 °C [329].

The main component of the oil is safrole, which may make up more than 90 % of the oil and determines its freezing point. (IFRA recommendation)

Production from trees that grow wild in Brazil, Paraguay, and Columbia exceeds that of North American sassafras oil, which is similar in composition. The main use of the oil is for the production of safrole and products derived from it (e.g., isosafrole and piperonal, see page 69).

Chinese sassafras oils (annual production about 950 t) are fractions, rich in safrole, that are obtained from oils of different species of the camphor tree (see Camphor Oils, page 90).

Savory oil is obtained by steam distillation of the whole dried herb *Satureja hortensis* L. (Summer savory) or *S. montana* L. (Lamiaceae) (Winter savory). It is a light yellow to dark brown liquid with a spicy odor, reminiscent of thyme or origanum.

d_{25}^{25} 0.875 – 0.954; n_D^{20} 1.4860 – 1.5050; $[\alpha]_D$ − 5 ° to + 4 °; phenol content: 20 – 59 %; saponification value: max. 6; solubility: 1 vol in 2 vol of 80 % ethanol at 25 °C; solutions in 10 vol of ethanol may be slightly hazy [330].

Several qualities of savory oil exist, depending on the *Satureja*species used. The main cultivation areas are France, Spain, some of the Balkan countries, and some midwestern states of the United States. Characteristic of savory oil is its high content of carvacrol [*499-75-2*].

Carvacrol

Savory oil is used mainly in the food industry, e.g., for flavoring sauces and soups.

Spearmint oil, see Mint Oils, page 107.

Spike oil, see Lavandula Products, page 105

Star anise oil is obtained by steam distillation of the star-shaped fruits of *Illicium verum* Hook. f. (Illiciaceae), an evergreen tree growing in Vietnam and China. It is a colorless to pale yellow liquid, which solidifies on cooling.

d_{20}^{20} 0.979 – 0.985; n_D^{20} 1.5530 – 1.5560; $[\alpha]_D^{20}$ $-2°$ to $+2°$; solubility: 1 vol in 3 vol of 90 % ethanol; *fp* min. 15 °C [331].

The main component of star anise oil, as in anise oil, is *trans*-anethole (86 – 93 %, determined by GLC). Pure anethole can be obtained by rectification (see page 64). Star anise oil has replaced true anise oil derived from *Pimpinella anisum* in the production of natural anethole.

Star anise oil and its product, anethole, are used primarily in the alcoholic beverage industry (anise liquors), but also for flavoring food and toothpaste.

Styrax oil and styrax resinoid are obtained from styrax balsam, which is collected from the artificially injured trees, *Liquidamber orientalis* Mill. (Asia Minor) and *L. styraciflua* L. (Central America) (Hamamelidaceae).

Styrax resinoid is a light grey to dark grey-brown viscous liquid that is prepared by solvent extraction. It has a sweet balsamic, slightly grasslike odor and is used in perfumery as a fixative.

Steam distillation of the balsam gives *styrax oil*, a light yellow liquid that contains a relatively large amount of cinnamic acid, which partially crystallizes. Styrax oil has a sweet-balsamic odor with a styrene-like top note. It is used in perfumery in flowery compositions. (IFRA recommendation).

Tagetes oil (Marigold oil) is produced by steam distillation of the flowering plants *Tagetes minuta* L. (*T. glandulifera* Schrank., Asteraceae). The main producers are in France, South Africa, and India. The oil is a yellow to dark orange liquid with a strong, aromatic-fruity odor. Its main components are *cis*-ocimene, dihydrotagetone, tagetone, and *cis*- and *trans*-ocimenone.

It is used in accentuated flowery fragrances and in aroma compositions to achieve fruity effects. (IFRA recommendation)

Tarragon oil (estragon oil) is produced by steam distillation of leaves, stems, and flowers of *Artemisia dracunculus* L. (Asteraceae). It is a colorless to pale yellow liquid with a characteristic, spicy, delicate estragon odor reminiscent of liquorice and sweet basil.

d_{20}^{20} 0.918 – 0.943; n_D^{20} 1.5080 – 1.5180; $[\alpha]_D^{20}$ $+2°$ to $+6°$; acid value: max. 1; ester value: max. 18; solubility: 1 vol in 4 vol of 90 % ethanol [332].

The main component of tarragon oil is estragole (methylchavicol, see page 89), which may make up > 60 % of the oil.

Worldwide production of tarragon oil only amounts to a few tons per year. It is used mainly in aroma compositions, smaller quantities are employed in perfumery.

Tea tree oil is obtained by steam distillation of leaves and twig tips of *Melaleuca alternifolia* Cheel, *M. linariifolia* Sm. and *M. dissitiflora* F. Mueller, and other *Melaleuca* species, which are trees growing in Australia (Myrtaceae). It is a colorless to pale yellow liquid with an earthy, spicy odor.

d_{20}^{20} 0.888 – 0.906; n_D^{20} 1.4750 – 1.4800; $[\alpha]_D^{20}$ $+5°$ to $+15°$; cineole content: max. 15 % (by GLC); terpinen-4-ol content: min. 30 % (by GLC); solubility: 1 vol in 2 vol of 85 % ethanol [333].

Tea tree oil is used in perfumery for creating certain nuances and for earthy notes. In addition there is an increasing interest for using this oil in aroma therapy. Annual production is ca. 150 t.

Thuja oil, see Cedar Leaf Oil, page 92.

Thyme oil is obtained by steam distillation of flowering plants of *Thymus zygis* L. var. *gracilis* Boissier (Lamiaceae). Thyme oil is not to be confused with white thyme oil; see under Origanum Oil. Thyme oil is a red or reddish liquid with a strong, characteristic, spicy-phenolic odor and a sharp, lasting taste.

d_{20}^{20} 0.910 – 0.937; n_D^{20} 1.4940 – 1.5040; $[\alpha]_D^{20}$ $-6°$ to $-1°$; total phenol content: min. 38 %, max. 56 %; solubility: 1 vol in 3 vol of 80 % ethanol [334].

The main constituents of thyme oil are thymol and carvacrol (up to 60 %); for structures of these compounds, see p. page 63, page 116. Other chemotypes of *T. vulgaris* are limited to specific areas and yield, e.g., oils that contain geraniol, linalool, α-terpineol, and cineole; these oils are of minor importance.

Thyme shrubs grow in France, Spain, Algeria, and Morocco. Spain is the main producer of the oil. Thyme oil is used mainly for flavoring foods and oral hygiene products, but is also used in perfumery to create spicy, leathery notes. Because of its high phenol content, thyme oil has germicidal and antiseptic properties.

Tolu balsam resinoid is produced by extraction of the balsam of *Myroxylon balsamum* (L.) Harms (Fabaceae). It is a dark orange brown mass with a sweet, resinous, long-lasting odor, reminiscent of hyacinth. An essential oil is also distilled from the balsam.

Tolu balsam resinoid contains a fairly large amount of benzyl and cinnamyl esters of benzoic and cinnamic acid.

Both the resinoid and the balsam are used in perfumery, mainly for their fixative properties.

Tonka bean absolute is prepared by solvent extraction either directly from so-called Tonka beans or via the concrete. Tonka beans are the seeds of fruits from *Dipteryx odorata* (Aubl.) Willd. (Fabaceae).

Tonka bean absolute is a solid or crystalline mass with a sweet, caramel-like odor, reminiscent of coumarin. In perfumery tonka bean absolute is used as a fixative and produces a dry sweetness in men's fragrances.

Tree moss absolute, see Oakmoss Absolute, page 110.

Tuberose absolute is obtained by solvent extraction, via the concrete, from the blossoms of *Polianthes tuberosa* L. (Agavaceae). The plants are cultivated in Morocco, Egypt, and India. Tuberose absolute was formerly produced in southern France by enfleurage. It is an orange to brown liquid with a sweet-narcotic blossom odor and is used in modern, flowery perfume compositions.

Turpentine oils (→ Turpentines) are used in large quantities by the fragrance industry as starting materials for the manufacture of single fragrance and flavor compounds. Turpentine oils are obtained either from balsams or from the wood of various Pinaceae species. They are less valuable as odor materials than the oils obtained from needles, young twigs, and cones (see Pinaceae Needle Oils, page 113). Nevertheless, they are used either as such or indirectly as fragrant solvents for perfuming household products. IFRA recommends that these oils should only be used when the level of peroxides is kept to the lowest practical level.

Balsam turpentine oil is obtained from the resins of living trees of suitable *Pinus* species by distillation at atmospheric pressure and temperatures up to 180 °C, or by other fractionation methods, which do not change the terpene composition of the resins. *Wood turpentine oils,* on the other hand, are generally obtained by steam distillation of chopped tree trunks, dead wood, or of resin extracted from this wood. *Sulfate turpentine oil* is produced as waste in the manufacture of cellulose by the sulfate process and is also a wood turpentine. Pine oil is another wood turpentine oil that is obtained by dry distillation of suitable pine and fir trees, followed by fractionation.

Balsam and wood turpentine oils are colorless liquids with a mild, characteristic odor. Oils obtained by dry distillation often also have a phenolic note. The specifications of turpentine oils are listed in Table 5 [335].

Worldwide production of turpentine oils is ca. 300 000 t/a, of which approximately one third is produced in the United States and Canada as sulfate turpentine oil. Other major producers are the CIS, Scandinavia, and China.

The main components of all turpentine oils are terpene hydrocarbons. The balsam and sulfate turpentine oils produced in the South-

Table 5. Specifications of turpentine oils

Parameter	Type of turpentine oil			
	Balsam	Wood, steam distilled	Sulfate	Wood, dry distilled
d_4^{20}	0.855 – 0.870	0.855 – 0.870	0.860 – 0.870	0.850 – 0.865
n_D^{20}	1.465 – 1.478	1.465 – 1.478	1.465 – 1.478	1.463 – 1.483
Distillate up to *bp* 170 °C, %	90	90	90	60
Evaporation residue, %	2.5	2.5	2.5	2.5
Acid value	1	1	1	1

east of the United States contain mainly α- and β-pinene (60 – 70 % and 20 – 25 %, respectively); *Pinus palustris* Mill. (long leaf pine) gives the (+)-enantiomers and *Pinus caribaea* Morelet (slash pine) gives the (−)-enantiomers. The remaining constituents are *p*-menthadienes, oxygen-containing terpenoids, and anethole. In contrast with the Scandinavian and Russian turpentine oils, the American oils contain very little 3-carene or camphene. Large amounts of the American oils are separated by fractional distillation into their components, which are used as starting materials in the manufacture of fragrance and flavor compounds. European turpentine oils originate mainly from Portugal, where distillation of *Pinus pinaster* Aiton resin or wood gives a turpentine oil that consists of 70 – 85 % (−)-α-pinene and 10 – 20 % (−)-β-pinene [336].

Valerian oil is obtained by steam distillation of well-dried ground roots of *Valeriana officinalis* L. (Valerianaceae). It is a yellow-green to yellow-brown liquid with an extremely strong, characteristic, penetrating odor. The oil becomes dark and viscous on aging or on exposure to air.

d_{25}^{25} 0.942 – 0.984; n_D^{20} 1.4860 – 1.5025; $[\alpha]_D$ − 28 ° to − 2 °; acid value: 5 – 50; saponification value: 30 – 107; solubility: 1 vol in 0.5 – 2.5 vol of 90 % ethanol at 25 °C, solutions are clear to opalescent when up to 10 vol of ethanol is added [337].

The main component of the oil is (−)-bornyl acetate, but it also contains other bornyl esters (e.g., bornyl isovalerate), terpene and sesquiterpene hydrocarbons, as well as free isovaleric acid, which contributes strongly to the odor of the oil.

Valerian is cultivated in Belgium, northern France, east Germany, Poland, Hungary, and southern Russia. The so-called Kesso roots obtained from *Valeriana officinalis* L. var. *angustifolia* Miq., cultivated in Japan, give a much larger yield of oil.

Valerian oil is produced in limited quantities and is used in flavor and fragrance compositions and, to a small extent, in pharmaceutical preparations.

Vanilla extract (an oleoresin) is produced by extraction of the pods of *Vanilla planifolia* Andrews or *V. tahitensis* J. W. Moore (Orchidaceae) with a polar solvent (e.g., methanol, ethanol, or acetone, which may also contain water). The composition of the extract depends on the type and amount of solvent used. Generally, the percentage of vanillin in the extract (yield 25 – 30 %) is 3 – 4 times higher than that in the pods.

Vanillin and phenol derivatives are primarily responsible for its aroma. The main producers of *V. planifolia* pods are Madagascar, the Comoro Islands, and Réunion (Bourbon); *V. tahitensis* pods are grown mainly in Tahiti.

Vanilla extracts are used extensively in chocolate and baked products, but even more so in ice cream.

Verbena oil is produced by steam distillation of the leaves of *Aloysia triphylla* (L'Hér.) Britton [*Lippia citriodora*(Lam) Humb., Bonpl. et Kunth, *L. triphylla* (L'Hér.) Kuntze, (Verbenaceae)]. It is a light yellow liquid with a delicate lemon odor.

d_{20}^{20} 0.890 – 0.920; n_D^{20} 1.4820 – 1.4880; $[\alpha]_D$ − 18 ° to − 10 °; content of carbonyl compounds (calculated as citral): 32 – 38 %; solubility: 1 vol in 1 vol of 90 % ethanol.

The major components of "true" verbena oil are citral (ca. 40 %), geraniol, and nerol (ca. 5 % each).

The verbena plant, originates in South America, but is cultivated mainly in southern France. The oil is used in fine fragrances. IFRA recommendation.

Vetiver oil is produced by steam distillation of the roots of the grass *Vetiveria zizanioides* (L.) Nash (Poaceae), which grows wild or is cultivated in many tropical and subtropical countries. The oil is a brown to reddish-brown, viscous liquid with a characteristic precious-wood- and rootlike, long-lasting odor. The following specifications are for oil produced in Haiti:

d_{20}^{20} 0.980 – 1.001; n_D^{20} 1.5160 – 1.5270; $[\alpha]_D^{20}$ + 22 ° to + 46 °; acid value: min. 1, max. 14; ester value: 5 – 35; carbonyl value: 23 – 59; solubility: 1 vol in 2 vol of 80 % ethanol at 20 °C.

The tenacity of the highly complex vetiver oil is attributed to its high sesquiterpene content. The ketones α-vetivone [*15764-04-2*] and β-vetivone [*18444-79-6*], which form up to 10 % of the oil, as well as khusimol [*16223-63-5*] (up to 15 %) and its derivatives, contribute significantly to its odor [338].

α-Vetivone

β-Vetivone

Khusimol

The oil contains a considerable number of bi- and tricyclic primary, secondary, and tertiary sesquiterpene alcohols, called vetiverols or vetivenols. These alcohols, as well as their acetates, are valuable fragrance materials. Since several varieties of vetiver grass exist and since fresh as well as air-dried roots are distilled under conditions that vary with the producer, the quality of the commercial oils differs considerably. Oil yields are up to 3 %. The main producers are Indonesia, China, and Haiti (ca. 300 t/a).

Vetiver oil is used in fine fragrances for long-lasting precious-wood notes. It is also used as starting material for vetiveryl acetate (see page 41).

Violet leaf absolute is obtained by solvent extraction, via the concrete, from the leaves of *Viola odorata* L. (Violaceae), which is grown predominantly in southern France.

The absolute is a dark green to brown liquid with a strong, green odor. The main constituent of the volatile fraction is 2-*trans*-6-*cis*-nonadienal [*557-48-2*] (violet leaf aldehyde).

Violet leaf absolute is used frequently in perfume compositions, but only in very low concentration because of its intense odor.

Ylang-ylang and cananga oils are essential oils that are obtained from two subspecies of the cananga tree.

1) *Ylang-ylang oils* are obtained by steam distillation of freshly picked blossoms of *Cananga odorata* (Lam.) Hook. f. et Thomson (Annonaceae). These cananga trees normally grow to a height of 20 m but are pruned to a height of 2.10 – 3.00 m and flower throughout the year. The oil is produced mainly in Madagascar and the Comoro Islands. Four fractions are collected at progressively longer distillation times and are known as "Extra", "I", "II", and "III". They are all pale to dark yellow liquids with a characteristic floral, spicy, balsamic odor. The first fractions are the most valuable; they have a higher density and a higher saponification value. Specifications of fractions obtained from Comoro Island oils are given in Table 6 [339, 340].
   The compositions of the various oil fractions depend on the duration of distillation. The first fraction, ylang-ylang oil Extra, has the highest content of strongly odoriferous constituents such as *p*-cresyl methyl ether (about 8 %), methyl benzoate (about 5 %), (−)-linalool (about 11 %), benzyl acetate (about 30 %), and geranyl acetate (about 4 %). The other fractions contain increasing amounts of sesquiterpene hydrocarbons (mainly caryophyllene and germacrene D), which can reach 70 % in ylang-ylang III. Components such as *p*-cresol, eugenol, and isoeugenol are important for the odor, although they are present only in low concentration.
   Ylang-ylang Extra and I are used mostly in fine fragrances; ylang-ylang II and III are employed in soap perfumes.
2) *Cananga oil* is produced by steam distillation of the flowers of *Cananga odorata* (DC) Hook. f. et Thomson subsp. *macro-*

Table 6. Specification of ylang-ylang oils from the Comoro Islands

Parameter	Ylang-ylang fractions			
	Extra	I	II	III
d_{20}^{20}	0.955 – 0.976	0.938 – 0.960	0.925 – 0.945	0.906 – 0.925
n_{D}^{20}	1.498 – 1.506	1.501 – 1.509	1.502 – 1.511	1.503 – 1.513
$[\alpha]_{D}^{20}$	$-40°$ to $-20°$	$-46°$ to $-25°$	$-60°$ to $-35°$	$-72°$ to $-45°$
Acid value	<2	<2	<2	<2
Ester value	140 – 185	100 – 160	75 – 115	45 – 75

phylla (Annonaceae). The yield, based on the weight of the flowers, is ca. 1 %: The oil is a light to dark yellow liquid with a characteristic, floral, slightly woody odor.
d_{20}^{20} 0.906 – 0.923; n_{D}^{20} 1.4950 – 1.5030; $[\alpha]_{D}^{20}$ $-30°$ to $-15°$; solubility: 1 vol in 1 vol of 95 % ethanol at 20 °C (solution may be turbid); acid value: max. 2; ester value: 13 – 35 [341].
The qualitative composition of cananga oil resembles that of ylang-ylang III oil, but is distinguished by its higher caryophyllene content (30 – 40 %).
Cananga oil originates almost exclusively in Java, where the flowers are collected throughout the year; annual production is 30 – 50 t. The oil is used mainly in soap perfumes.

4. Quality Control

Quality control of fragrance and flavor substances, as well as the products derived from them, comprises the comparison of sensory, analytical, and if necessary, microbiological data with standards and specifications. To a large extent these have been established in official specification collections (Pharmacopoeias, ISO, Association Française de Normalisation (AFNOR), Essential Oil Association, Merck Index).

In the past few decades, a precise analytical methodology has been developed for sensory evaluation and has proved to give reliable results [342]. Analytical determination of identity and purity aids greatly in establishing the acceptability of fragrance and flavor materials.

Single fragrance and flavor compounds are characterized by generally accepted physical constants, such as density, refractive index, optical rotation, and melting point. The advantages of these parameters are their speed of measurement and the possibility of comparison with other laboratories; therefore, they will continue to be indispensable. In addition, these measurements can be done more and more by robots controlled by computers.

Determinations of content by chemical parameters, such as ester and carbonyl values, are being increasingly supplemented by chromatographic procedures such as GC and HPLC and by spectroscopic techniques (UV, IR, NIR, and NMR).

Standardization of specifications for complex fragrance and flavor materials, such as essential oils and animal secretions, is far more difficult than for single compounds. In addition to organoleptic and physical properties, the content of certain typical components is determined. Problems concerning the natural, botanical, and geographical origins of these products are solved by using modern chromatographic and spectroscopic analytical techniques (and combinations such as GC – MS). Furthermore the determination of chiral properties of the molecules by enantioselective capillary GC has become a routine method. Isotope ratio mass spectrometry (IRMS) reveals the stable isotope ratios of the bioelements C, H, O, N, and S and the positional isotope analysis can be performed by Site-specific Natural Isotope Fractionation – NMR (SNIF – NMR) [343]. These methods have become very effective tools for authenticity control.

The analysis of trace components (halogens, heavy metals, and pesticides) in flavors and fragrances that are used in foods and cosmetics is becoming increasingly important. Radioactivity values in materials of natural origin are also monitored.

5. Economic Aspects

The flavor and fragrance industry has grown from an artisanal development into an industrial business. The total market for these product categories is estimated to about $ 16×10^9, Europe and North America being the leading markets with shares of about $ 5.4 and 4.1×10^9, respectively. Total annual growth rates till 2005 are forecasted to reach about 4.5 %, growth in Europe and North America will be below 3 %. In general it is predicted that sales of flavors will grow by about 5.5 % and fragrances on a whole by about 3 %.

The flavor and fragrance industry has undergone a great degree of consolidation since the mid-1990s. The top ten flavor and fragrance producers have combined sales in excess of $ 9×10^9, corresponding to about 55 % of the total value. The remaining 45 % of the market are shared by more than 1000 other companies, many of them serving only one to three customers. Out of the top ten companies, four have annual sales in excess of $ 1×10^9, namely Givaudan and Firmenich of Switzerland, IFF of the USA and Quest, which is affiliated with ICI. Takasago of Japan also reports sales in excess of $ 1×10^9, however its sales in the flavors and fragrances field are less than that. The remaining top ten companies, in addition to the aforementioned, are Dragoco and Haarmann and Reimer, both in Germany, Universal Flavors in the USA, and Hasegawa in Japan. The last one of this group, BBA of the USA, has recently been taken over by IFF. In conclusion, it can be foreseen that further consolidation will increase the market shares of these top ten companies over the next five years.

6. Toxicology and Environmental Aspects

The addition of flavor and fragrance compounds to foods, cosmetics and toiletries, and other consumer products is intended to improve the quality of those products. So these chemicals must not have adverse effects on health or well-being. To avoid any problems caused by perfumed consumer products, the fragrance industry decided to build up a self-regulatory system.

Already in 1966 in the USA the Research Institute for Fragrance Materials, Inc. (RIFM, Two University Plaza, Suite 406, Hackensack, N.J. 07601) was established for the sole purpose of fragrance safety. As an independent nonprofit organization, RIFM has a continuing program, testing fragrance materials of good commercial quality. All judgements in matters pertaining to the evaluation of safety are made exclusively, and independently by an international expert panel of toxicologists, pharmacologists, and dermatologists drawn from the academic world. Those results are published as 'RIFM monographs' in the journal 'Food and Chemical Toxicology' [344] and in the Internet under www.rifm.org/data/start.cfm. These monographs contain specifications and data on biological activity (e.g., acute, short-term, and long-term toxicity, toxicokinetics, and metabolism).

In 1973 national associations of fragrance manufacturers have formed the International Fragrance Association (IFRA, 8, Rue Charles Humbert, CH-1205 Genève, Switzerland), an international organization with scientific aims concerned with all aspects of safety evaluation and regulation of the fragrance industry. IFRA represents over 100 fragrance manufacturers in 15 countries and edits guidelines advising against the use of fragrance materials under conditions that might provoke irritation and sensitization reactions or phototoxic effects (see Section 1.5.2). The activities of RIFM and IFRA are harmonized by a Joint Advisory Committee. Similarly to IFRA, the International Organization of the Flavor Industry (IOFI, same adress as IFRA) publishes lists of naturally occurring and nature-identical flavor components, which may be used up to given concentrations, and of artificial flavor substances that are considered to be nontoxic.

For more than 40 years the Flavor and Extract Manufacturers' Association's (FEMA) Expert Panel Food Additives conducts a comprehensive program of safety evaluation of flavoring substances under the authority of Section 201(s) of the Federal Food, Drug, and Cosmetic Act. FEMA publishes compendiums with flavor components commonly known as GRAS.

In the 1980s and especially in the 1990s a growing awareness developed that flavor and fragrance chemicals can also affect the environment. So the Material Safety Data Sheets of fla-

vors and fragrances (MSDS, see EEC Directive 91/155/EEC) now contain in addition to the toxicological information also ecological information, mainly: biodegradability and aquatic toxicity. In most countries, the use of flavor and fragrance materials in consumer products is extensively regulated.

Recent Discussions. In 2002 *nitromusks* were identified in surface water, fish, and human fat and milk samples. Due to their low biodegradability these substances – having been used for 100 years – accumulate in the environment. In addition a relatively high log (partition coefficient octanol – water) (log $P_{ow} > 5$) shows that these substances are lipophilic and therefore accumulate also in fat tissue. RIFM has initiated the execution of various studies: acute and subchronic toxicity, irritation, sensitization and photosensitization potential, genotoxicity, carcinogenicity bioassay; studies on dermal absorption and pharmacokinetic.

Reports of *polycyclic musks* in the environment have also prompted a review of the safety of these important fragrance ingredients and similar studies as for nitromusks were conducted. For both groups the following summary is valid: Margins of safety based on the no-adverse-effect levels from subchronic studies are sufficient to conclude that direct exposure from use of these materials in fragrances or indirect exposure from their presence in the environment pose no significant risks to human health. Their environmental risk assessment is the subject of separate reviews.

The discussions on the nitro and polycyclic musks have given increased evidence of the importance of knowing as much as possible about properties of fragrance materials such as biodegradability and partition coefficient octanol – water.

1. Introduction

Flocculants are used to optimize the separation of the solid phase from the liquid phase in aqueous suspensions. These suspensions usually consist of organic or inorganic particles, which are of finely divided to colloidal consistency and are distributed in water as a dispersion medium. With smaller particles, the suspension is more stable, i.e., the lower is the tendency for the particles to agglomerate and sediment. However, addition of a flocculant drastically increases the rate of particle sedimentation so that a clear, supernatant liquid is obtained. The settled sludge can then be filtered rapidly or centrifuged, resulting in a more efficient separation.

In this article, a distinction is made between organic and inorganic flocculants in accordance with the international convention.

Inorganic flocculants are mostly aluminum or iron salts that form insoluble hydroxide precipitates in water. Impurities in the water are adsorbed onto the sedimenting precipitate flocs and are thus removed from the water. A combination of inorganic and organic flocculants is frequently employed in the treatment of water.

Organic flocculants are natural or synthetic water-soluble polymers. They may also be called sedimentation, clarification, filtration, or centrifugation aids, according to their final use. The ability of synthetic polymers to increase the sedimentation rate of suspensions was first observed in 1939 [4]. The flocculation effect exerted by synthetic water-soluble polymers was discovered at the beginning of the 1950s at BASF, and at about the same time, Cyanamid filed a patent application for polymeric flocculants in Canada [5]. Flocculants produced by BASF were first used successfully in 1955 for the clarification of washing water in German collieries [6]. Shortly afterwards, Dow Chemical introduced their flocculants into the United States market. Since then, organic flocculants have steadily gained in importance and are now used worldwide in many branches of industry and in water-treatment plants.

2. Classification of Flocculants

2.1. Inorganic Flocculants

The most important inorganic flocculants are the trivalent salts of aluminum and iron, as well as activated silica, and are listed in Table 1.

2.2. Natural Organic Flocculants

The group of natural organic flocculants includes water-soluble starch [*9005-25-8*] [7], guar gum, alginates [*9005-38-3*], and products based on chitin [8], glue, and gelatin [9]. Owing to their low relative molecular masses (10 000 – 100 000), these flocculants are only moderately efficient. Despite the very low cost of some of these natural products, the cost-to-performance

Table 1. Inorganic flocculants

Type	Formula	CAS registry number	Comments
Alum	$Al_2(SO_4)_3 \cdot 14\,H_2O$	[*7784-31-8*]	used as a powder (17 wt % Al_2O_3) or 50 wt % solution (8.5 wt % Al_2O_3)
Poly(aluminum chloride)	$Al(OH)_{1.5}(SO_4)_{0.125}Cl_{1.25}$	[*7446-70-0*]	obtained by partially hydrolyzing $AlCl_3$ [*7446-70-0*], used as a solution (10 wt % Al_2O_3)
Sodium aluminate	$NaAlO_2$	[*1302-42-7*]	used as a powder and solution
Iron(III) chloride	$FeCl_3$	[*7705-08-0*]	used as a powder (100 wt % $FeCl_3$) or solution (35 – 45 wt %)
Iron(III) sulfate	$Fe_2(SO_4)_3$	[*10028-22-5*]	used as a granulate
Iron(III) sulfate chloride	$FeClSO_4$	[*12410-14-9*]	obtained by oxidation of $FeSO_4$ with chlorine in solution, used as a solution (30 – 40 wt %)
Iron(II) sulfate	$FeSO_4 \cdot 7\,H_2O$	[*7782-63-0*]	used as a crystalline powder
Sodium silicate (activated silica)	Na_2SiO_3	[*1344-09-8*]	used as a solution

ratio of synthetic flocculants is considerably more favorable due to their very high relative molecular masses. Consequently, natural organic flocculants have steadily declined in importance. Only soluble starch was able to maintain its market position in certain fields for any length of time, e.g., in the preparation of bauxite (red mud flocculation [10], → Aluminum Oxide, Chap. 3.1.4.) and the purification of water (→ Water). Starch was chosen for the latter application because, unlike synthetic organic flocculants, its use did not require legal permission. Flocculants based on natural organic polymers are now of little importance and are not, therefore, further discussed.

2.3. Synthetic Organic Flocculants

2.3.1. Chemical Structure

The chemical structure of synthetic organic flocculants determines their flocculating properties. They are water-soluble polymers which can be classified into nonionic polymers [11], and ionic polymers (polyelectrolytes); the latter can be further subdivided into anionic, cationic, and amphoteric types [12]. Examples of flocculants from each of these groups are given in Table 2.

Nonionic Polymers. Other nonionic homopolymers not cited in Table 2 can be produced from 1-vinyl-2-pyrrolidone [*88-12-0*], *N*-vinylformamide [*13162-05-5*], methoxyethylene [*107-25-5*], etc. Poly(vinyl alcohol) [*9002-89-5*] is synthesized by hydrolysis of poly(vinyl acetate). Very high molecular mass poly(ethylene oxide) [*25322-68-3*] is obtained by polymerizing ethylene oxide over special catalysts, e.g., alkaline-earth carbonates or aluminum alcoholates (C_1–C_4) [13], [14]. Nonionic homopolymers are, however, of little commercial importance as flocculants.

Ionic Polymers. The most important ionic polymeric flocculants are copolymers derived from acrylamide [*79-06-1*] and a charged comonomer [→ Polyacrylamides and Poly(Acrylic Acids)].

Anionic Polymers. Almost all anionic polymeric flocculants are synthesized as homopolymers or acrylamide copolymers of the alkali-metal or ammonium salts of acrylic acid [*79-10-7*]. Methacrylic acid [*79-41-4*], maleic acid [*6915-18-0*], ethylenesulfonic acid [*1184-84-4*], 4-styrenesulfonic acid [*98-70-4*], and 2-methyl-2-[(1-oxo-2-propenyl)amino]-1-propanesulfonic acid [*15214-89-8*] are also used as comonomers in acrylamide copolymers, but are of little practical importance.

Cationic Polymers. Other water-soluble comonomers are used for the production of cationic polymers in addition to those listed in Table 2, the most important being the following: substituted acrylamide and methacrylamide salts [16–19]; *N*-vinylformamide [*13162-05-5*] and *N*-vinylacetamide [*5202-78-8*], which are polymerized and hydrolyzed in alkaline or acidic media to "vinylamine" copolymers [*593-67-9*] [20–23]; and salts of *N*-vinylimidazole [*1072-63-5*],

2-vinylpyridine [*100-69-6*] or 4-vinylpyridine [*100-43-6*].

Table 2. Synthetic organic flocculants

Type	Formula	CAS registry number	Comments
Polyacrylamide	$\left[CH_2CH(CONH_2)\right]_n$	[*9003-05-8*]	main nonionic organic flocculant
Poly(ethylene oxide)	$\left[CH_2CH_2O\right]_n$	[*25322-68-3*]	nonionic; can be used, like polyacrylamide, with other flocculants
Poly(sodium acrylate)	$\left[CH_2CH(COO^-Na^+)\right]_n$	[*9003-04-7*]	important anionic polyelectrolyte, used mostly as a copolymer with acrylamide
Poly[2-(*N*,*N*,*N*-trimethylamino)-ethyl acrylate] (chloride salt)	$\left[CH_2CH(COOCH_2CH_2\overset{+}{N}(CH_3)_3)\right]_n\ Cl^-$	[*54076-97-0*]	important cationic polyelectrolyte, used mostly as a copolymer with acrylamide
Polyethylenimine	$\left[N(CH_2CH_2NHCH_2CH_2)(CH_2CH_2NHCH_2CH_2NH_2)\right]_n$	[*26913-06-4*]	cationic polyelectrolyte with a high charge density in its neutralized form
Poly[*N*-(dimethylamino-methyl)acrylamide]	$\left[CH_2CH(CONHCH_2N(CH_3)_2)\right]_n$	[*25765-48-4*]	cationic polyelectrolyte formed from polyacrylamide, formaldehyde, and a secondary amine by the Mannich reaction [a], mostly neutralized or quaternized

Water-insoluble or sparingly water-soluble comonomers can also be incorporated, provided the resulting copolymers are still soluble in water.

Cationic homopolymers and copolymers of dialkyldiallylammonium chlorides, e.g., diallyldimethylammonium chloride [*7398-69-8*], can be produced by free-radical polymerization; these polymers are composed of chains bearing cyclic structures [24–28]. The polyamines are another important class of cationic flocculants and are obtained by polycondensation. The starting materials are alkylene dichlorides or epichlorohydrin and ammonia, low molecular mass alkylene polyamines, or polyaminoamides [29–33]. Polycondensation of ethyleneimine [*151-56-4*] yields polyethylenimines.

Amphoteric polymers that bear both anionic and cationic charges are of little practical importance as flocculants.

2.3.2. Production Requirements

The raw materials used to synthesize organic flocculants are described in Section 2.3.1.

High molecular mass polymers are required for efficient flocculation (cf. Section 3.4). Thus, very strict requirements are imposed on the purity of the starting materials, especially the monomers. Contamination by inhibitors or by chain-transfer or cross-linking agents must be avoided. Water is the preferred solvent because other solvents either yield polymers of lower molecular mass due to transfer reactions or pose an ecological risk.

A second important prerequisite for obtaining a high molecular mass is a polymerization temperature that is as low as possible. The polymerization temperature depends largely on the choice of initiator. Conventional free-radical initiators, such as alkali-metal persulfates and peroxides, are being superseded by azo initiators, which decompose at lower temperatures, e.g., 2,2′-azobis(2-amidinopropane)hydrochloride, 2,2′-azobis(2,4-dimethylvaleronitrile). Alternative initiators are redox catalysts (e.g., ascorbic acid) and UV and γ-radiation [34–39]. Attempts are also being made to achieve homogeneous temperature distribution by removing the heat produced during polymerization as efficiently as possible from the reaction vessel, e.g., by using evaporative cooling, special monomer feed techniques in thin layers [36], [40], [41], or two-phase systems. A method for trapping the heat of polymerization with endothermic reactions has also been described [42], [43].

Synthetic organic flocculants are marketed as liquids (either solutions or emulsions) and solids.

Solutions. Polycondensation in an aqueous solution is an important technique for producing polyamine flocculant solutions. A polymer content of ca. 50 wt % can be attained.

When acrylamide is copolymerized in solution, the high molecular masses that are desired result in highly viscous, gel-like solutions, which are difficult to handle when the polymer content exceeds 10 wt %. Special metering and solubilizing equipment is required [44]. These solutions are important starting materials for the manufacture of solid flocculants.

Emulsions. Emulsion flocculants are more important than solution flocculants and are made by the polymerization of water-in-oil emulsions [45–50] (for details of emulsion polymerization, → Polymerization Processes). A concentrated aqueous monomer solution is emulsified with emulsifiers in a dispersion phase that usually consists of a high-boiling mixture of aliphatic hydrocarbons. The particle size of the emulsions is 0.1 – 10 μm and their viscosity is low, usually less than 1500 mPa · s. Polymerization is then started by adding oil- or water-soluble initiators; azo initiators are preferred, but the use of UV irradiation has also been described [51]. Wetting agents are added to the polymerized water-in-oil emulsions prior to use; the emulsions are then inverted in water [52]. Variations on this simple batch method dissipate the heat of polymerization more efficiently either by evaporative cooling [53], [54] or by special monomer feed techniques [55], [56]. These methods yield emulsions with a polymer content of 25 – 45 wt %. An even higher polymer content can be obtained by azeotropic distillation of the internal aqueous phase and some of the hydrocarbon mixtures [57].

Water-in-oil emulsions are easy to handle despite their high polymer content and require no drying with the attendant risk of product damage. However, the starting materials are more expensive and the stability of the emulsions is limited.

Solids. Liquid products can be dried to give powders. Drying methods include precipitation of the polymers with low molecular mass alcohols or acetone in a heavy-duty mixer, drying on rollers, spray-drying, azeotropic distillation with inert organic solvents, and irradiation with microwaves. Water-in-oil emulsions are not often dried because of the relatively high initial cost of the raw materials. Solid flocculants are usually obtained from aqueous polymer solutions. High polymer concentrations are used to reduce drying costs. The solutions form firm gels, which are cut into small pieces and dried. The particle size of the final powder is adjusted by milling and sieving.

An industrially important alternative for obtaining solid flocculants is based on polymerization of a water-in-oil suspension [58–61] (for details of suspension polymerization, → Polymerization Processes). The concentrated aqueous monomer solution is emulsified in the presence of special protective colloids in a hydrophobic phase. The hydrophobic phase may be a low-boiling aliphatic compound, an aromatic hydrocarbon, or a halogen derivative of the latter. Polymerization is started with water-soluble initiators and proceeds by evaporative cooling to produce polymer beads that contain water and have a particle size of 0.1 – 0.5 mm. The water is then removed by azeotropic distillation, the hydrophobic phase serving as an entraining agent. The solid product is obtained after separation of the organic solvent, drying, and sieving.

Solid flocculants with high molecular masses can also be prepared by precipitation polymerization in, for example, *tert*-butanol or its mixtures with water [62], [63], but this method is less important.

The advantages of solid products are their high flocculant concentration, which results in lower marketing costs and increased stability. Their disadvantages are the necessity for a drying stage, with the associated risk of product damage, and their slow rate of dissolution. The latter problem has been largely solved by the development of modern dosing devices.

3. Flocculation Mechanisms

The stability of a suspension depends on the number, size, density, and surface properties of the solid particles (internal or dis-

persed phase) and on the density of the external phase or dispersion medium. The stability and destabilization of colloids, suspensions, and emulsions are discussed in detail elsewhere (→ Colloids, Chap. 5.,→ Colloids, Chap. 6.,→ Colloids, Chap. 7.; → Disperse Systems and Dispersants, Chap. 3., → Disperse Systems and Dispersants, Chap. 4.; → Emulsions).

In aqueous suspensions, the particle surface has an electrical (usually negative) charge, which, for example, in mineral solids originates from the dissociation of protons from surface hydroxyl groups belonging to silicate groups [64]. If counterions (e.g., Ca^{2+} or Mg^{2+}) are present in the surrounding water, they accumulate on the surface of the suspended particles, forming an ionic double layer [65]. The excess negative charge at the shear surface of the double layer (the zeta potential) can be measured with a zeta meter. As the zeta potential increases, the coulombic repulsion between the particles becomes stronger and the suspension is more stable.

Many authors distinguish between "coagulation" and "flocculation" [66]. *Flocculation* is usually taken to mean the process in which particles are interlinked by molecular chains with no change in the zeta potential (anionic and nonionic organic flocculants). *Coagulation,* however, is taken to mean the electrical neutralization of suspended particles, as brought about by iron and aluminum hydroxide.

Four models are used to explain how flocculants aid particle agglomeration. However, more than one of these mechanisms probably act simultaneously.

3.1. Double Layer Compression

As the cation concentration in the water increases, the thickness of the ionic double layer decreases (i.e., the double layer is compressed), thereby reducing the number of collisions between the particles and rendering the suspension unstable [67]. This mechanism accounts to some extent for the destabilization of suspensions by inorganic salts, especially by monovalent ions.

3.2. Specific Ion Adsorption

The mechanism of specific ion adsorption always applies when cations are bound chemically to the particle surface, e.g., by forming complexes with the surface atoms. Thus, the particle charge may be partially or completely neutralized [68], [69]. In the latter case, the particles no longer repel each other and the conditions for agglomeration are optimal.

Trivalent aluminum and iron salts are examples of flocculants that function in this way. In water they are partially or totally hydrolyzed to form positively charged dibasic, tribasic, or polymeric hydroxides that adsorb onto the particle surface and neutralize its charge according to their degree of hydrolysis.

3.3. Polymer Charge Patch

When cationic polymers are added to a suspension, they are adsorbed to the surfaces of particles with negative charge as described in Section 3.2. They neutralize the negative charge, but their charge density is higher than that of the particle surfaces. Thus, positively charged polymer centers (polymer charge patches) are formed on the particle surfaces and, in turn, come into contact with the negatively charged surfaces of other particles and also destabilize the suspension [70], [71]. Flocculation involving relatively low molecular mass cationic polymers (e.g., polyethylenimine) is thought to proceed by this mechanism.

3.4. Polymer Bridging

In polymer bridging, high molecular mass polymer chains are adsorbed onto the particle surface and form bridges between adjacent particles [72–75]. Adsorption occurs by electrostatic forces, van der Waals forces, hydrogen bonding, and chemical bonding. This model is used to account for the flocculation produced by high molecular mass organic flocculants. The bridging mechanisms of anionic, cationic, and nonionic organic flocculants are different.

Mineral (anionic) suspensions are generally flocculated with anionic polyelectrolytes for

economic reasons (e.g., in the coal mining industry). This is only possible beause the anionic particles are not suspended in deionized water, but in hard water. Water hardness varies and is primarily caused by divalent calcium and magnesium ions. These positively charged ions are adsorbed onto the negatively charged particle surface to form an ionic double layer. The positively charged ions face outward and allow the anionic flocculant to approach the particle closely enough to be adsorbed to its surface [72]. In this case, bridging is the result of a genuine chemical bond in which the divalent cations link the solid particles with the active groups on the polymer chain. However, hydrogen bonding may also play a role. Obviously, mineral suspensions cannot be flocculated in very soft water due to the absence of divalent ions. Therefore, the suspensions must be hardened with anhydrous lime prior to the addition of the polymer. Alternatively, cationic flocculants can be used.

Obviously, the probability that a polymer can be adsorbed simultaneously onto different particles and act as a bridge between them increases with an increase in its molecular mass. Accordingly, the most effective anionic flocculants have molecular masses of ca. $(10-20)\times10^6$. Thus, sedimentation is quicker and filtration is easier when large stable agglomerates or flocs are formed [76].

Since cationic flocculants are positively charged, they partially or completely neutralize negative charge on particle surfaces, and the polymer chains cross-link adjacent particles.

The only bridging mechanism that is available to nonionic synthetic flocculants, e.g., polyacrylamide and poly(ethylene oxide), is hydrogen bonding.

4. Uses

The fact that suspended solid particles can be made to agglomerate to form large, rapidly settling, easily filterable flocs is exploited to clarify suspensions and dewater the resulting sludges. Flocculants are added to accelerate settling in basins and to dewater sludge in vacuum filters, sand filters, belt filters, filter presses, and centrifuges. However, water purification is not the sole application of flocculants. Each branch of industry has its own priorities, which may be maximum recovery of a solid matter and/or the separation of a clear aqueous phase. Combinations of organic and inorganic flocculants can, to some extent, remove dyes and oily impurities from effluents.

If the density of the flocs is similar to that of the aqueous phase, they may float and not settle. Thus, flocculants may promote flotation, but this may be troublesome if solids of different composition are to be separated (coal and ore flotation) [77].

The most important uses of flocculants are summarized in Table 3.

5. Choice of Optimum Flocculant

Flocculant manufacturers now offer comprehensive ranges of anionic, cationic, and nonionic flocculants that differ from one another in the chemistry of their monomeric building blocks, the nature and size of their ionic charge, and their molecular mass [137]. It is not always easy to predict which flocculant is most suitable to obtain the desired sedimentation rate for a specific application. Broadly speaking, anionic and nonionic organic flocculants are best for neutral suspensions that consist primarily of inorganic solids, whereas cationic flocculants are best for neutral suspensions containing predominantly organic solids.

Figure 1. Relationship between the sedimentation rate of a suspension and the quantity of flocculant added
a) Weakly anionic flocculant; b) Strongly anionic flocculant

Inorganic flocculants are used mainly to clarify suspensions containing a low concentration

Table 3. Uses of Flocculants

Field of application	Use	Flocculant type∗	Reference
Mining industries			
Coal	clarification of washwater and flotation tailings,	a-PAA	[78], [79]
	filtration of concentrates,	a-PAA	[80], [81]
	dewatering of tailings	a-PAA, PEI, c-PAA	[82], [83]
Ores	clarification of flotation tailings,	a-PAA	[84–87]
	thickening and filtration of concentrates	PAA, a-PAA	
Potash	clarification of potash solutions	a-PAA	[88], [89]
	(hot solution and flotation processes),		
	dewatering of tailings	PAA, PEO	
Fluorite and barytes	clarification of flotation tailings	a-PAA	[90], [91]
Kaolin	thickening of kaolin slurries	a-PAA	[92], [93]
Salt works	clarification of raw brine, sludge dewatering	PAS, a-PAA	[94]
Phosphate	water recovery in mines,	PAA, a-PAA	
	filtration of gypsum,	a-PAA	[95–97]
	clarification of phosphoric acid	PAA	
Uranium processing	filtration of acidic or alkaline solutions	PAA, PEO	[98], [99]
Foundries and metalworking	clarification of water for scrubbing gas from blast furnaces, clarification of effluents from		
	sintering and pickling plants,	a-PAA	[100–102]
	purification of electrolytic solutions,	PAA, a-PAA	[103–105]
	clarification of electroplating effluents	a-PAA	[101]
Bauxite benification	thickening of red muds (Bayer process)	PAS	Aluminum Oxide, [106]
TiO_2 production	clarification of black liquor,	c-PAA, CCP	[107]
	filtration of TiO_2	PAA	
Paper industry	retention of kaolin and	PEI, c-PAA, PA	[108–114]
	dewatering of slurries on paper machines,	PEI, c-PAA, PA	
	pulp recovery	PEI, c-PAA, PA	
	effluent clarification and dewatering	a-PAA, c-PAA	
Communal and industrial water treatment plants	effluent purification,	IF, a-PAA	[115–117]
	thickening of activated sewage sludge,	c-PAA	[118]
	flotation of activated sewage sludge,	c-PAA	[119]
	mechanical dewatering of sewage sludge,	c-PAA	[120–124]
	phosphate precipitation	IF, a-PAA	[125]
Clarification of potable and non-potable water	flocculation of surface water,	IF, a-PAA	[126–128]
	clarification of wash water used to flush filters,	a-PAA	
	filter conditioning	a-PAA, PEI, PA	[129], [130]
Sugar processing	clarification of sugar juice, dewatering of sludge	a-PAA	[131–133]
Biotechnology	dewatering of biological sludges	PEI, PA, c-PAA	[134–136]

∗ CCP = cationic carbamoyl polymers; IF = inorganic flocculants; PA = poly(alkylene polyamines); PAA = polyacrylamide; a-PAA = copolymers of acrylamide and sodium acrylate; c-PAA = copolymers of acrylamide and cationic substituted (meth)acrylates, neutralized and quaternized; PAS = poly(sodium acrylate); PEO = poly(ethylene oxide); PEI = polyethylenimine.

of particulate material, e.g., in the purification of surface water to potable water. The voluminous hydroxide flocs adsorb both solid and dissolved contaminants. If the flocs sediment too slowly, the sedimentation rate can be accelerated by adding an organic flocculant.

pH Value. The pH is important in selection of a flocculant because it determines the degree of dissociation of anionic and cationic polyelectrolytes. Complete dissociation of the flocculant is desired, and anionic and cationic flocculants are, therefore, preferred for alkaline and acidic suspensions, respectively. Nonionic polymers are affected very little by the pH. In the case of highly acidic suspensions, nonionic polymers are often preferred to cationic flocculants for economic reasons.

Flocculant Addition. At a given flocculant addition rate, the suspension settles more slowly if its solid content increases or if its average particle diameter decreases [6]. However, the amount of flocculant that is required also depends on the strength of its ionic charge. Figure 1 illustrates the difference in behavior between a strong and a weak anionic flocculant in a neutral suspension.

Powder flocculants tend to clump when they are simply added to water, and a great deal of energy is needed to incorporate emulsions into water. Manufacturers supply instructions with their products and also offer simple devices for

overcoming the above-mentioned difficulties as well as problems encountered in continuous processes. Integrated semiautomatic and automatic equipment is commercially available. Polymeric flocculants are generally used as 0.05 – 0.1 wt % solutions. Inorganic flocculants are supplied in crystalline form or as aqueous solutions and are used as 10 wt % solutions.

Normally 0.1 – 0.5 g of flocculant is added per cubic meter of suspension in the thickener or settling basin. When sludge is dewatered with the aid of filters and centrifuges, 2 – 8 kg of flocculant per ton of dry sludge is necessary.

Laboratory Tests. When a flocculant is chosen, it is always helpful to carry out laboratory trials with a series of different flocculants [138]. Fresh suspensions must be used. Representative samples should be taken if the composition of the suspension varies considerably. The manufacturer's literature should be consulted for further details. The following tests can be used, depending on the intended application:

1) Sedimentation tests in a shaker provide information about the sedimentation rate and clarity of the supernatant [139]. Laboratory results can be helpful in calculating flocculant doses required in continuously operating thickeners, thus eliminating long trial periods in the initial period of use [140].
2) Filter plate tests (vacuum filtration).
3) Büchner funnel tests (filtration with and without vacuum) [141], [142].
4) Pressure filter tests [143].
5) Determination of filtration rate (capillary suction time) [144], [145].Tests 2 – 5 provide information about the dewatering of sludges, especially with regard to the thickness and moisture content of the filter cake and the filtration efficiency.
6) Determination of floc stability [143]; this test provides information about the dewatering of sludges in centrifuges.
7) Jar test [146]: In this test the flocculant is added to a suspension in a jar (beaker). Slow stirring induces the formation of voluminous hydroxide flocs that surround the slurry. The sedimentation and clarity of the test samples are compared after the stirrer has been switched off. This test is performed on slurries containing very little sedimentable material for which organic flocculants are generally unsuitable.
8) Dynamic flocculation measurement with the aid of a laser beam [147]. This method is also used for optimizing the flocculant metering rate in continuously operating systems.

6. Legal Aspects

The high molecular mass polymeric flocculants are not toxic in themselves. Certain precautions should be taken, however, because they all contain small proportions of residual toxic monomers [148], especially acrylamide. Legal controls apply when the flocculants are used in the manufacture of food, in the purification of potable water, or for the clarification of sugar juice.

A list of the flocculants that are approved by the EPA for water purification is printed annually in the United States [149]. Many other countries have their own regulations, but these regulations differ very little from each other. Generally, the residual monomeric acrylamide content must be less than 0.05 wt % of the polymer content; the amount of flocculant added to untreated water should not exceed 1 g/m^3 [150].

The United States regulations on the clarification of sugar juice [151] are generally observed worldwide; they stipulate that the residual acrylamide monomer content must account for less than 0.05 wt % of the polymer content, and the quantity of added flocculant must not exceed 5 g/m^3. Methods for determining the residual monomeric acrylamide content of polymers and the residual flocculant content of treated water have been described [150], [152].

7. Economic Aspects

In 1984, the use of synthetic organic flocculants (calculated as dry mass) in Western Europe was ca. 15 000 t and in the United States ca. 40 000 t, half of this being accounted for by polyacrylamides. Large markets also exist in Canada, South America, Africa, Australia, and Japan.

Of the inorganic flocculants, alum ($Al_2(SO_4)_3 \cdot 18\,H_2O$) enjoys the largest market share. In 1978, ca. 400 000 t was used in the

United States and ca. 150 000 t in Western Europe, in both cases almost exclusively for water treatment.

Representative worldwide producers of inorganic and synthetic organic flocculants are given in Tables 4 and 5.

Table 4. Representative worldwide producers of inorganic flocculants

Flocculant	Producers
Alum	Allied (USA)
	Amer. Cyanamid (USA)
	Boliden (Sweden)

1. Textile Fiber Floor Covering

Textile floor coverings have been highly appreciated in the human environment ever since textile manufacturing techniques were developed. They deliver an individually designed artificial ground which can be soft, warm, sound-insulating, and colored/patterned.

Global carpet production grew to 2.5×10^9 m^2 in 1999, of which 52 % was produced in the United States, 27 % in Western Europe, 9 % in the Asia/Pacific region, and 12 % in other regions of the world. World carpet fiber production amounted to 2.1×10^6 t in 1999. On the basis of area, the main fiber materials used worldwide are nylon (55 %), polypropylene (34 %), polyester (5 %), and wool (3 %). The majority of carpeting is used for residential fitted carpets and rugs (68 %); the remaining 32 % is split between commercial installations (e.g., offices, hotels, banks, schools, and retail stores), automotive and transportation, and outdoor carpeting [1].

For the production of carpets, either bulked continuous filament (BCF) or staple fiber can be used. Whilst BCF yarn experienced strong growth in the mass market during the 1980s and 1990s, staple fiber retains a very strong position in more upmarket segments. BCF yarns continue to gradually substitute staple fiber yarns, the substitution being driven by superior process economics along the value chain.

1.1. Fiber Production

The production of synthetic fibers for use in carpet manufacture starts with polymers, which are made from monomers (or intermediates) derived from crude oil. For example, Nylon 66, the most prevalent fiber material, is made from hexamethylenediamine and adipic acid. These react with one another to form a monomer (in this case known as nylon salt), which is then polymerized. The polymer is fed in the form of solid pellets or chips into the fiber-forming melt spinning machine. Alternatively, polymer production and fiber spinning can be coupled in a continuous melt-spinning operation. Melt spinning is used for the majority of synthetic fiber carpet yarns, including Nylon 66 and 6, polyester, and polypropylene. For a detailed discussion of fiber production and specific fibers, see → Fibers, 3. General Production Technology; → Fibers, 4. Synthetic Organic.

1.1.1. Staple Fiber

The molten polymer is extruded through shaped holes to form filaments, which are then quenched (cooled) so that they solidify. The filaments are collected in a large bundle, known as a tow or rope, consisting of hundreds of thousands of filaments. The rope is stored for further processing.

Natural fiber such as wool and, to a lesser extent, cotton, sisal, and silk, have an inherent crimp, which gives the fiber desirable value and esthetic properties, such as bulk (i.e., volume or space filling), and an ability to recover from deformation. Furthermore, most natural fibers are not continuous but instead have relatively short lengths. In a second processing operation, therefore, the synthetic fiber tow is drawn, crimped while in a relaxed state and heat-set. The tow is then cut into the desired staple fiber lengths and baled.

1.1.2. Bulked Continuous Filament

Bulked continuous filament yarn is so named because the fibers are used in continuous form (not cut, as with staple from synthetic and natural fibers), and the fiber is crimped (or bulked) during manufacture.

As with staple, filaments are extruded from the melt and quenched. They are then collected into yarn bundles comprising tens of filaments. The yarn is then drawn, crimped (bulked), and heat-set. Bulk is usually achieved by compression of the heated yarn into a small hot chamber whose dimensions determine the character of the bulk/crimp. After a residence time in the chamber sufficient to ensure heat-setting, the yarn is cooled, straightened under tension, and wound onto packages. The advantage of heat-setting is that, despite being straightened, the fibers retain a "memory" of the crimp and recover a major part of it when subjected to a combination of heat and moisture in subsequent processing at low tension. Generally, the character of crimp achieved in BCF yarns is not the same as that of staple yarns; a wider range of bulk in the finished carpet can be achieved with BCF. Yarn properties also depend on other production parameters, such as draw ratio.

1.1.3. Polymer Selection

Polymer selection is one of the most important determining factors in the balance of properties achievable in the carpet, as well as the cost and ease of fiber and subsequent carpet manufacture.

Nylon (polyamide 6 and 66) is the major carpet fiber polymer in use today, followed by polypropylene, polyester [poly(ethylene terephthalate)], and wool. Nylon is widely used because its molecular structure imparts outstanding abrasion resistance, excellent recovery from high strains, and excellent dyeability, lending the polymer great versatility, performance, and durability. Polyamide 66 is made from hexamethylene diamine and adipic acid, whereas polyamide 6 is produced from caprolactam. While the two polymers are similar

in many ways, the less symmetrical molecular structure of nylon 6 results in a more open structure and lower crystallization potential.

Polypropylene (PP) has gained market shares over the last few decades because of lower raw material cost and the low technological entry barrier for fiber extrusion. Several carpet mills have started to produce polypropylene fibers in house (vertically or backward integrated carpet manufacture). (The same is true to some extent of Nylon 6 and polyester, but Nylon 66 yarns remain more difficult to produce, and their manufacture is still exclusively the preserve of specialized yarn manufacturers.) Polypropylene carpets have lower appearance retention than Nylon carpets, but are appropriate for less demanding applications. PP is usually produced as pigmented (spin-colored, solution-dyed) staple or BCF, since an economical route to a dyeable PP fiber has not been established.

Polyester fibers are available mainly in staple form; polyester is less versatile in dyeing and less resilient in carpet than Nylon.

Wool, which has traditionally been regarded as a premium fiber, tends (due to lower abrasion resistance) not to perform as well as Nylon in like-for-like carpets, though carpets made from wool tend to be more expensive. Wool quality can vary widely.

1.1.4. Fiber Design

Fiber design is at least as critical to carpet properties as polymer selection. The esthetic properties and performance characteristics of a carpet are determined by a variety of fiber-related factors. These include:

- Yarn thickness or size, which is measured for BCF yarns in *decitex* (dtex = g/10 km) or *denier* (g/9 km), and varies typically from 600 to 2500 dtex (as singles yarns). Staple yarn thickness is measured in Nm (metric count, m/g) or c.c. (cotton count, 840 yards/lb).
- The thickness of individual filaments within a yarn bundle, often referred to as dpf or decitex per filament.
- Fiber cross section (Fig. 1), dictated by the shape of the extrusion hole and various polymer and production parameters. All melt-spun fibers can be shaped at extrusion, but this is best exploited by the polymer types most able to withstand abrasion.
- Luster or brightness, most commonly controlled by the addition of a delustrant (usually TiO_2) to the polymer, but also affected by fiber cross section and by voids, striations, and spherulites, which may be induced in spinning, and by crimping.
- Character and degree of bulk or crimp

Fiber design and its impact on carpet properties is further discussed in Section 1.2.

Figure 1. Carpet fiber cross sections
A) Round; B) Trilobal; C) Square hollow filament

1.2. Yarn Preparation

The short, crimped staple fibers must be spun together to form a staple yarn before further use. Both staple and BCF yarns can then be tufted directly as singles yarns into carpet from producer packages. Alternatively, a number of further processing steps can first be employed, depending on the esthetic and performance characteristics desired in the carpet. These include twisting and heat-setting, and intermingling.

1.2.1. Staple Yarn Processing

Staple yarn production involves opening of the fiber bales, possibly blending with other staple fibers, carding (to align the individual fibers), drawing (drafting), and spinning or twisting (to lock the fibers into the final yarn).

The use of staple allows the blending of fibers of different cross section, luster, or dyeability. This relatively intimate blending at the fiber level provides different styling options from those achieved by plying or twisting different yarns, as described below. Even different materials are blended to obtain desired carpet properties. For

example, an 80/20 wool/nylon blend provides markedly improved wear performance versus 100 % wool. Blending, of course, can also have a beneficial effect on the uniformity of the yarn produced and therefore the final carpet.

1.2.2. Twisting, Heat-Setting, and Intermingling

Depending on the desired carpet esthetic and performance characteristics, yarns of the same or different lusters, decitexes and/or dyeabilities may be combined by using a twisting and heat-setting process or an air entanglement/intermingling process.

Twisting. Two (or sometimes more) singles yarn packages are plied and twisted around each other to form a twisted yarn ready for heat-setting. *Direct cabling* (Volkmann, Verdol: see Fig. 2) is the most common twisting technique.

Figure 2. Operating diagram of a Verdol cable twister
a) T_3, plied yarn; b) Bucket yarn tensioner; c) Creel yarn balloon; d) Balloon restraining ring; e) Storage disk; f) Spindle; g) T_2, creel yarn; Tension (T) is adjusted via weighted disks or other devices at the package

Twisting has several purposes. While simple plying achieves a desired total yarn decitex, twisting provides the tuft integrity (tuft definition, texture) which is characteristic of saxony and hard twist (friezé) carpet styles. The amount of twist put into the yarn influences not only the initial appearance or texture of the carpet, but also the retention of this texture, which degrades in use according to the severity of traffic exposure. Increased twist level, however, increases yarn cost and results in loss of carpet bulk because of compression of the yarn crimp. The twist level used for a given style is therefore a balance of many factors. The yarns twisted together are usually identical, but dissimilar yarns may be paired to achieve additional styling flexibility.

Heat-Setting. The twisted yarn structure is sufficiently stable to allow winding onto packages, but it must be heat-set to lock in the twist and withstand the stresses of carpet dyeing and finishing and the traffic received in use. Also, yarn ″leanness″ can occur because the crimp has been pulled out in the various winding and packaging operations. If the yarn is heated while relaxed, much of this crimp, and hence yarn bulk, can be recovered. Therefore, both bulk recovery and setting of the structure are necessary so that the yarn remains stable in its intended end-use area.

For Nylon 66 or 6, setting can be achieved in a hot dry atmosphere at 180 – 220 °C or, alternatively, in saturated steam at 120 – 140 °C. Machines made by Suessen and Superba embody these two continuous heat-setting processes, which have now largely displaced the earlier autoclave batch process. BCF is primarily Superba steam set, while Suessen hot air setting is the preferred method for staple in North America.

Intermingling is another technique used to increase styling options in carpet design. The effect achieved is different to that obtained by twisting and heat-setting. Two or more singles yarns are unwound and passed together through a small chamber to which compressed air is applied. The yarns become intermingled or comingled with each other and are then rewound as a single yarn. They do not require subsequent heat-setting. Intermingling is carried out predominantly with BCF yarns, and more often to

combine dissimilar rather than identical yarns, for example yarns with different dyeabilities.

1.3. Production of Textile Floor Coverings

1.3.1. Flooring Types and Manufacturing Methods

The major types of textile floor coverings are tufted, woven, and nonwoven. Further manufacturing techniques include fusion bonding, flocking, and knitting.

Tufting is currently the fastest, most economical, and most automated method for producing carpets (Fig. 3). Needles held on a needle bar are each threaded with a pile yarn and pushed through a primary backing fabric. Under the backing, a hook or looper catches and holds the yarn to the desired pile height (Fig. 3 A – C). For cut-pile yarn, a knife cuts the loops as they accumulate on the looper; for loop-pile yarn, the hook withdraws and leaves a loop (Fig. 3 D and E). Carpet density is determined by the number of stitches per unit length in the tufting direction, by the spacing between needles, and by yarn thickness.

Thicker yarns require coarser needles with larger spacing. Common spacings between needles (gauges) range from 0.16 cm for European fine velours up to 0.8 cm (1/16, 5/64, 1/10, 1/8, 5/32, 3/16, 5/16 inches). Pile heights vary between 3 and 50 mm. Pile weights consequently range from 300 to 2500 g/m^2. The average tufted pile weight in Europe is 580 g/m^2 versus ca. 1000 g/m^2 in North America (worldwide average 840 g/m^2). The needle bar of a tufting machine can be moved sideways, and this enables the creation of tuft patterns if the needles are fed with yarns of different types. A wider range of patterning options is available on machines with double sliding needle bars, full repeat scrolls, and other modifications (e.g., Graphics, Cobble Colortec, Tuftco).

The application of a latex lock coat to the underside of the primary backing is the preferred method of locking the filaments together and into the primary backing. A secondary backing is then usually applied to enhance dimensional stability, strength, and lay-flat stiffness and to protect the underside of the carpet. It provides the contact for fixing the textile floor covering to the ground on installation. In the past, residential carpets in continental Europe (low pile weights) usually had a foam secondary backing. Recent landfill regulations and restrictions, as well as efforts to simplify carpet construction for environmental reasons, have led to the introduction of textile layers (woven fabrics; nonwoven needled fleeces, often made from polyolefin or polyester with a content of recycled material), which provide similar underfoot comfort and thermal and acoustic insulation. These textile backings have largely displaced foam. In countries where piles are typically higher, where underlays are used (UK, North America), and in commercial installations, a very thin fabric provides the interface between the latex and the underlay or floor.

Woven carpets are produced by the Wilton or the Axminster method; the main differences between them are the design of the loom and the weave used. In Wilton production, the pile yarn is carried through the backing, whereas in Axminster, the pile yarn is inserted in the backing.

Flocked carpets and fusion-bonded floor coverings with an upright pile use melt or normal adhesives to anchor fibers or yarns to a backing (Fig. 4). *Needled floor coverings* (fleeces, nonwovens) are produced by needle punching with optional subsequent fiber bonding. They can be homogeneous or consist of more than one layer (heterogeneous).

Figure 4. Flocked-pile carpet

Figure 5. Manufacturing principle of needled textile floor covering
Reproduced by courtesy of ISO

In needle punching, layers of loose fibers are passed under a bank of barbed needles (Fig. 5). The needles catch filaments and entangle the layers of fibers with each other. Special techniques have been developed which allow the creation of needled pile floor coverings (e.g., Dilour).

In thermobonding, contact points between fibers are melted together by heat treatment. This requires fibers with low melting point, core-sheath two-component fibers with low melting polymer sheaths, or melt adhesives.

Bonding compounds (e.g,. latex) act as adhesives. Needled floor coverings can be fully impregnated or back coated.

A backing layer can be used to add volume, enhance stability, allow for easier installation, etc.

Fleeces are used as inexpensive commercial floor coverings in Europe and feature in special applications such as outdoor and automotive carpeting.

1.3.2. Carpet Constructions

Carpets can be grouped into two major construction classes: loop pile and cut pile (Fig. 6).

Loop pile carpets (Fig. 6 A) can have level pile surfaces, patterned loops, or loops with two or three different pile heights to give a textured effect. Styling beyond pile height and carpet density is achieved by coloration of the carpet or yarn. Loop pile carpets, which achieve good durability by virtue of the loop construction and therefore do not require twisted, heat set yarns, are usually produced by direct tufting of BCF singles or intermingled yarns. However, many new loop styles now use twisted and often heat set yarns.

Cut pile carpets can be further subdivided into a variety of different constructions. These include saxony, hard twist (friezé), cut-and-loop, shag, velour (velvet), and COC. *Saxony carpets* (Fig. 6 B) use twisted, heat-set yarns having 1.4 – 2.4 turns per centimeter (3.5 – 6 turns per inch). This results in regular pinpoint tufts. *Friezé* (*hard twist*) carpets (Fig. 6 C) contain more highly twisted yarns, which are kinked before the heat setting process. This leads to irregular tuft-end formation on yarn cutting (during tufting) and variable light reflection from either bent or upright fibers at the pile surface. In *Cut-and-loop* carpets (Fig. 6 D), some of the tufts are cut and others remain whole loops, forming a pattern. *Shags* are high pile, very low density saxony carpets. The pile height exceeds 2 cm, but the individual tufts lie flat rather than standing upright. Carpets of *velour* (velvet) construction (Fig. 6 E) use staple yarns with little or no twist. The yarn stands upright in the carpet, and adjacent tufts are not visible as single entities, so that the surface appears uniform. Velours form an important segment of the residential market in continental Europe. *COC* is an acronym for cross-over-cut and refers to constructions in which Nylon singles yarns of different dyeabilities or yarns of different color are directly tufted with a sliding needle bar to form a pattern. They are found primarily in the continental European commercial sector. Velours and COCs are examples of the direct tufting of staple and BCF singles yarns, respectively. In the United Kingdom and North America, by contrast, staple yarns are twisted and heat set and used to make the other carpet structures described above. The majority

of BCF yarns used for cut-pile are also twisted and heat set before tufting. The vast majority of staple fibers are used in cut pile carpets.

1.3.3. Coloration and Finishing

Of all manufacturing operations in a carpet mill, coloration and finishing have perhaps the most significant effect on the visual and tactile properties of the end product. *Coloration* can refer to dyeing or to printing of white (typically Nylon) carpet material. Both continuous and batch dyeing processes are in commercial operation. Depending on the fiber selection, plain colors or multicolored effects can be achieved from one dye liquor. In a printing process, multicolored designs/patterns are produced by screen or spray printing. *Finishing* can refer to the application of a chemical aftertreatment, such as a protective stainblocking or anti-soil treatment. Shearing of the pile to improve the final surface uniformity of the carpet is an example of a mechanical finishing process. The last finishing step for tufted carpets is the application of a latex lock coat and then a secondary backing.

Dyeing. Tufted carpets made from white Nylon yarns are being increasingly dyed on continuous dyeing machines. Quick-change color applicators (Küsters, Fleissner) are used to speed process changes. In the continuous process, dye liquor is poured evenly over the carpet running below. After color application, the carpet runs into a steamer with vertical loops (festoons), and is heated with saturated steam for 2 – 6 min, during which the dyes are fixed onto the fiber. Water rinsing, hydro-extraction, and drying follow. In the less productive batch method, carpets are dyed in winches (becks). Here, a section of carpet runs in a loop through a full dyebath with temperatures up to boiling point for 40 – 60 min.

Acid leveling dyes are used for most Nylon carpets in residential and commercial end uses. This class of dyes allows the best color uniformity with good fastness properties in later end use. For combinations of standard and chemically modified Nylon (differential-dye yarns), which allow multicolor effects from a single dyebath, acid leveling, acid contrast, and cationic dyes are used. Metal-complex dyes are mainly used for automotive carpets, which require the highest standards of dye lightfastness, only achievable with this class of dyes.

Standard polyester and polypropylene are not commercially dyeable on current piece-dyeing equipment at atmospheric pressure. To avoid high-temperature dyeing ($> 100\,°C$ at > 0.1 MPa), carrier-free dyeable polyester, which is dyeable with disperse dyes, has been developed, and offers at least a limited styling flexibility. Most PP is colored by addition of pigments to the polymer melt during yarn manufacture.

Printing. White tufted Nylon carpets can be printed on flatbed screen printing machines or rotary screen printing machines, which allow the highest production speeds (30 – 50 m/min). The spray printing machines, Chromojet (Zimmer) or Millitron (Milliken), similar in principle to an ink-jet printer, run at lower speeds but are more flexible in terms of design possibilities and design change. Because the risk of poor color uniformity is much lower in printing, many kinds of acid and metal-complex dyestuffs are in use for standard prints. For the widely used resist and displacement printing techniques, specially selected groups of acid and metal-complex dyes are used, in combination with appropriate resist and blocking chemicals.

After color application the prints are run through a horizontal steamer for 3 – 6 min in saturated steam for color fixation, followed by water rinsing, hydro-extraction, and drying.

1.4. Carpet Properties and Performance

1.4.1. Carpet Esthetics

Color, pattern, and structure are the most obvious elements of the *visual esthetics* or appearance of a carpet, and are dictated by polymer/fiber choice, carpet construction, yarn choice (BCF/staple, singles/twisted, heat-set/intermingled), and coloration. Further important visual factors can be described in terms of luster, sparkle, glitter, sheen, clarity, brightness, dullness, chalkiness, etc. These are influenced by fiber design (Section 1.1.4), the shape of the fiber cross section (Fig. 1), mattness/brightness, crimp, yarn, and filament decitex.

The *tactile esthetics* of a carpet are influenced by many of the same factors; filament and yarn decitex (thickness/size), twist level of the plied yarn, crimp level of the filaments, and carpet construction, including pile height and stitch density.

1.4.2. Carpet Performance

The visual and tactile esthetics listed in Section 1.4.1 describe a new carpet. The performance characteristics of a carpet in use are also very important, and requirements vary from end use to end use.

Appearance Retention. Carpet appearance retention or "newness" retention in use has several aspects. It includes the loss of texture due to traffic (leading to damaged and opened tufts and consequent deterioration of surface texture), fiber loss, and recovery from compression after a weight (e.g., furniture) is removed. Appearance retention also covers changes to colors and patterns, whether due to fading (poor dye lightfastness) or blurring (due to deterioration of surface texture of the carpet). Further end use specific requirements include, for example, the ability to withstand the high downward and rotational forces exerted by castor chair wheels (office environments), and bleach resistance (hospitals).

Appearance retention depends on the nature of the pile fiber (basic molecular structure as well as subsequent processing), on carpet construction, and on carpet installation. Fiber material plays an important role in all mechanical aspects, whereby Nylon 66 has the best performance and is hence the fiber of choice for high-traffic commercial installations and premium residential carpets. The fiber cross section, delustrant content, bulk level, yarn decitex, and decitex per filament are significant factors. For example, fiber cross section and filament decitex are critical to wear performance. Carpet construction and the appropriate choice of yarn are also important. The floor performance of velour and loop-pile carpets is dependent on the density of the construction, determined by pile yarn mass and height. Using a bulkier yarn also increases the apparent density. The tightness of the yarn structure is a significant factor as well. Performance can be improved by increasing the twist or entanglement of the yarn. In saxony carpets, the most important factor is the twist level of the yarn. A low twist level is ca. 1.4 turns per centimetre (3.5 turns per inch) in singles yarn and in plied yarn. A minimum of two turns above primary backing is recommended for good appearance retention, which for cut-pile carpets like saxonies is most apparent in the tip definition of the tufts.

Pattern and color contrast of a textile floor covering also influence appearance retention by hiding physical changes in the surface structure.

The topic of appearance retention is complicated by the fact that some of the factors listed directly influence the amount of physical change that occurs in the carpet in use, while others affect the degree to which the change is visible, and some affect both.

Static electricity can be generated by the separation of the shoe sole and carpet pile material when walking on a carpet in a dry room climate. The increase in body voltage per step depends on the charge generated between the separated materials (rate of charge vs. rate of dissipation) and on the relative humidity, which has a marked effect on carpet resistance. This phenomenon is not limited to synthetic carpet fibers, but occurs with wool as well. Significant body voltages can be created in several ways, including by rising from furniture. Dissipation of charges (decay rate) is most effectively achieved by the addition of antistatic (conductive) filaments to the pile fiber in combination with a conductive lock coating. Electric charge can then be dissipated from the body through the carpet, even under dry conditions, preventing build up of voltages likely to be perceived as electric shocks. An alternative, but less durable solution for carpet installations in low-traffic areas, is the use of antistatic topical treatments. Computer rooms require particularly good antistatic protection.

Soiling refers to dirt on the carpet (rather than staining) and is basically a surface-transfer phenomenon in which dirt from shoe soles is transferred to the fiber surface of the carpet and vice versa. Airborne dirt usually plays a minor role. Dirt consists mostly of a blend of small inert particles, such as silicates, phosphates, oxides, and carbonates, held together by various amounts of

fatty organic materials and moisture (agglomerate size ca. 2 μm). It is first deposited at the top of a carpet but gradually migrates into the pile as traffic exposure continues.

Any fiber property that affects the size and nature of the carpet's exposed fiber surface will have a direct effect on soiling. This is the reason why coarse fibers with smooth surfaces and low surface area, in shapes that cannot trap soil, are best suited to reduce the soiling propensity. The chemical affinity of dirt particles for carpets is successfully reduced by surface application of fluorochemical coatings (e.g., polyfluoroalkylurethanes).

In addition to reducing the amount of soil deposited per traffic exposure, the visibility of soil can be reduced by proper carpet color selection, and by making fibers less transparent by addition of delustrants to increase light scattering. A particularly effective way to hide soil through light scattering is to incorporate voids into the fibers. Hollow fibers with low surface area and three to six voids (e.g., Fig. 1 C) are therefore preferred for commercial carpet installations where high traffic levels are expected.

Staining. Another feature of carpet fibers is their *staining* propensity. Nylon, which by virtue of its chemical nature is the most flexible fiber for all coloration methods – an advantage in offering consumer choice and at the production stage – is more prone to staining by, for example, food acids and beverages than some other substrates. Stain-resist or stain-blocking systems are applied which elevate Nylon's stain resistance to the level of polypropylene and polyester. Even coffee stains can be avoided with suitable systems [2].

Flammability of carpets is largely determined by fiber material, carpet construction (the denser the better), latex fillers, and secondary backing. Of all pile materials, wool can most easily be treated with flame retardants. Among the synthetic fibers, Nylon 66 performs best due to its high ignition temperature, whereas polypropylene burns most easily. This is a further reason for the limited use of polypropylene fibers in commercial installations. Carpets in transportation (particularly aircraft) end uses have very stringent flammability requirements.

Color Fastness. In addition to dye lightfastness, wash and rubbing fastness, resistance to fading in the presence of high NO_x and ozone levels is important for some end uses or geographical regions. Resistance to high sunlight and temperature exposure is critical in automobiles.

Health and hygiene issues carry increasing weight in modern society. Textile floorings have variously been blamed for poor indoor air quality, the propagation of dust mites (to the excreta of which, some people are allergic) and the harboring of other allergens and microbes. Many recent studies, however, show carpets to have a positive influence. For example, in combination with adequate and regular cleaning, carpets act to trap dust out from the air, reducing the amount of breathable dust (and potential allergens) in the atmosphere, thus improving air quality. Due to the relatively low humidity levels in carpets, they play a very limited role as breeding grounds for dust mites, which prefer bedding and other furniture. Studies conducted on Nylon 66 have demonstrated that it is essentially nontoxic through both the expected dermal route to exposure as well as by other possible but unlikely routes (oral and inhalation). Nylon 66 will not support mildew or bacteria, nor is it eaten by moth larvae [5]. The role of carpeting in the prevention/mitigation of noise pollution, as a safe, non-slip surface, and as a thermal insulator is increasingly recognized.

1.4.3. Test Methods

A system of carpet tests and classification schemes has been developed. End use recommendations for particular carpets are derived from these.

While a global classification for textile floor coverings is still pending, a common standard (EN 1307) has been agreed upon within Europe. This involves certain basic requirements such as

- Acceptable color fastness (to light: ISO 105-B02; to wet and dry rubbing; ISO 105-X12; to water: ISO 105-E01)
- Fiber bind [fuzzing and loss of mass (fiber loss), in preparation: ISO 11856]

It also introduces Use Classes (1 – 4) and Luxury Rating Classes (1 – 5).

Use Class reflects the resistance to wear (fiber loss; Lisson test ISO 12951 and appearance retention (Vettermann drum or Hexapod drum: ISO 10361, assessment of changes in appearance: ISO 9405). The Luxury Rating depends on carpet type (tufted, woven, flocked), thickness of pile (ISO 1766), mass of pile per unit area (ISO 8543) above primary backing, and number of tufts per unit area (ISO 1763).

Further properties are listed in EN1307 for particular end uses. These include:

- Castor chair suitability (EN 985, ISO 4918 in preparation)
- Electrical properties (walking test: ISO 6356, and vertical resistance: ISO 10965, at 25 % relative humidity)
- Acoustic properties (acoustic insulation from impact noise: ISO 140-8; acoustic absorption: ISO 354)
- Thermal resistance (ISO 8302)
- Suitability for use in periodically humid conditions such as bathrooms (dimensional stability: ISO 2551; higher color fastness to wet and dry rubbing: ISO 105-X12)
- Suitability for use on stairs (ISO 13746, in preparation)
- Fraying behavior (ISO 10833, in preparation).

Globally recognized tests do exist for soiling (Kappasoil ISO 11378-1 and drum test ISO 11378-2) and are in preparation for staining (ISO 13750) and flammability (Radiant Panel ISO 9239-1). For appearance retention, there is more reliance in North America on floor or "walker" trials (in tandem with laboratory tests like the Vetterman Drum) than is the case in Europe.

Needled floor coverings have their own classification system in Europe (EN 1470 needled pile floor coverings: EN 13297).

1.5. Disposal and Recycling

The majority of used carpets are currently still disposed of in landfill, though some are now incinerated with energy recovery. Carpets are a complex and intimate mixture of many different and incompatible materials: various polymers, adhesives, natural fibers, chalk, dyes, and dirt resulting from use (silicates, metal oxides, and organic matter). Collection and identification and the nature of the product make effective recycling anything but simple, but new legislation and improving process economics are powerful forces for change.

Several companies and major industry consortia in North America and in Europe have invested considerable effort in recent years, and significant progress has been made in the areas listed below:

- Some fiber manufacturers include melt-recycled plastics in new fibers.
- Carpet construction is becoming simpler and more recovery-friendly with the substitution of foam backing by more easily handled textile fleeces (which themselves can include recycled material)
- The polymer type in carpet pile and/or backing can now be identified with a new generation of spectroscopic analysers, either online or with portable instruments.
- Mechanical separation processes have been developed which are capable of separating the different carpet materials with varying degrees of purity. These can then be recycled, usually through a remelting process and generally to lower grade end uses (car parts, synthetic lumber, etc.). There are several such recycle programs operational in both North America and Europe.
- Chemical recycling is now available at least at pilot plant level for nylon polymer types in post-consumer carpet waste [6]. Polyester can also be depolymerized, but there is as yet no process for carpet waste. PP cannot be depolymerized into its constituent building blocks.

A number of pilot collection and recycle schemes are operating in North America and Europe and include collection, sorting, separation, remelting, chemical recycling, and energy recovery. Significant advances are to be expected by 2010.

2. Resilient Floor Covering

2.1. Introduction

Resilient flooring is a family of flooring products that includes such materials as linoleum, asphalt tile, rubber and vinyl flooring. The term resilient refers to the ability of these flooring materials to deform and recover from the compressive forces caused by the dynamic action of foot fall, cart wheels and casters, and the static loads of appliances and furnishings. Resilience distinguishes this group of flooring products from carpeting, wood, ceramics, and stone.

Types of Resilient Flooring. Resilient flooring is produced in two basic formats: sheet and tile. inthe case of vinyl flooring each has, with some exceptions, a distinctly different composition and manufacturing process, whereas rubber flooring employs essentially the same process and formulation for both forms.

Economic Aspects. The market for flooring is divided into two distinct segments: residential and commercial. The total area of existing residential floor space in the United States in 1998 was about 17×10^9 m^3, of which an estimated 16.2 % was covered with resilient flooring material, the remainder being covered with carpet, wood, ceramic tile, etc. Most residential resilient flooring is used in kitchens and baths, and some in foyers and family rooms.

The total commercial and institutional U.S. floor space in 1998 was approximately 36 billion square feet (3.4×10^9 m^3, excluding warehousing, manufacturing areas, and parking garages. Resilient flooring, both vinyl and rubber, constituted about 25.5 % of this area, carpet 56.5%, and others (stone, wood, ceramic, etc.) 18 %. Market segments for resilient flooring in the commercial and institutional area include mercantile, health care, education, light industry, offices, and banks.

The total apparent hard surface flooring consumption for 1998, including U.S. manufacturer shipments and imports, but excluding exports, amounted to $\$5.4 \times 10^9$, of which resilient flooring constituted 44.2 %.

History. [7–10]. The resilient flooring produced today evolved from painted fabric or floor cloth that was laid over board flooring to provide a decorative, washable surface and to keep out drafts from the cracks between the floor boards. Several attempts, dating back as far as the 1600s, were made to establish an industry to manufacture floor cloth and oil cloth. The invention of oil cloth is recorded in a 1627 patent. A patent from 1763 describes a floor covering made by coating fabric with a mixture of resin, tar, Spanish brown, beeswax, and linseed oil.

In 1844, a floor cloth made from India rubber, sawdust, and cork, named Kamtulicon, was introduced. At about the same time, waterproof fabrics coated with rubber became quite popular and drove the price of rubber up to the point where it became uneconomical for flooring use. A patent was issued to Frederick Walton in 1860 for an oxidized linseed oil intermediate called linoxyn which made possible the production of Linoleum, a name coined by Walton to differentiate it from the rubber-based Kamtulicon. In 1864 Linoleum was commercially introduced in England by Walton, Taylor & Co. This was essentially the beginning of the modern resilient flooring industry.

Linoleum is based on a binder system of oxidized drying oils, resins, and gums, filled with ground cork, wood flour, whiting, and pigments. Although it has excellent wearing characteristics, linoleum suffers from degradation by alkaline hydrolysis and is therefore unsuited for applications where alkaline moisture is present, e.g., on concrete subfloors in contact with the ground. It may also be damaged by frequent washings and stripping of wax polishes. Because of these limitations and the versatility of PVC-based flooring, its production was discontinued in the United States in 1973.

In those applications where linoleum was not suitable because of its sensitivity to moisture and alkalinity, such as on subgrade concrete, asphalt tile was used. This product was based on asphalt binders or, for lighter colored tiles, coumorone indene or hydrocarbon resins, filled with asbestos and limestone. Asphalt tile is essentially obsolete today.

2.2. Linoleum

Linoleum is experiencing a resurgence in popularity in the North American market because

of its use of natural and renewable raw materials and its unique design capabilities. Expected sales in 1999 are about 3 % of the total U.S. resilient-flooring market [11].

Production. Linseed oil and dryers (i.e., catalysts for oxidation) are combined and partially oxidized in a reactor. At a certain stage in the process, melted resins are added to form linoleum cement. When the right consistency and degree of oxidation is achieved, the linoleum cement is extruded, cut into billets, dusted with wood flour, and further aged to continue the oxidation process. It is then blended with the fillers and pigments in a high-intensity mixer and calendered or milled into sheets. If the finished product is to be a solid color flooring material or desk top material, it may be calendered directly to a backing of jute or a glass scrim. To form variegated colors, accent sheets are sliced or diced to appropriate sizes and calendered with a base color to form a jaspé. If this step gives the finished design, the material is calendered to a backing. If a marbled pattern is desired, unbacked jaspé sheets are cut into strips and cross-sheeted parallel to the calender nip and calendered. The resulting sheet is then laminated onto a backing.

The linoleum must be cured. It is festooned in tall ovens with about 18 – 28 m in each loop and cured at elevated temperature for 2 – 3 weeks. The cured product is finish coated with acrylic or nitrocellulose lacquer, inspected, and cut to length, generally the length of one loop.

Historical processes include inlaid linoleum, in which die-cut shapes from various colored and patterned sheets were laid into matching die-cut spaces in base sheet; and stenciled linoleum with "scratch mix" granules, mottled, and placed into pattern position through thick metal stencils. The scratch mix was produced by running a pin-studded roll against the linoleum composition while it was worked on a two-roll mill.

2.3. Vinyl Flooring

Although rubber flooring enjoys a significant market share, the dominant types of resilient flooring manufactured today have a binder system based on poly(vinyl chloride), PVC. This material is well suited for this application because: (1) it can tolerate high levels of inert filler, (2) it is clear and colorless, (3) it is inherently fire resistant, (4) it can be effectively plasticized to a wide range of flexibilities, and (5) it is not adversely effected by moisture or alkali. When moderately filled and plasticized it retains a high proportion of its inherent strength and durability.

Vinyl or PVC flooring was first introduced by Dynamit Nobel in 1934 under the trade name Mipolam [10]. Today there are many types of vinyl flooring in the market, both in sheet and tile form.

The U.S. custom is to refer to these products as vinyl flooring, whereas they are commonly called PVC flooring in Europe. This has led to some confusion in the American market with imported flooring products, which are sometimes thought to be based on different polymers. These terms should be considered synonymous in the flooring trade.

2.3.1. Raw Materials

Poly(Vinyl Chloride) Resins. Both vinyl chloride homopolymers [→ Poly(Vinyl Chloride)] and vinyl chloride/vinyl acetate copolymers are used in the production of resilient flooring. As a general rule, vinyl chloride homopolymers are used in sheet flooring and solid vinyl tiles, while vinyl composition tiles usually contain copolymers of vinyl chloride and vinyl acetate.

The weight-average molecular mass M_w of the resins most useful in flooring ranges from 40 000 to 200 000. The higher molecular mass polymers are frequently used in flooring wear layers because of their greater ultimate tensile strengths and abrasion resistance, whereas the lower molecular mass polymers, because of their lower melt viscosity, are most useful in producing foams for cushioned flooring and saturants for glass scrim reinforcements.

Flooring manufacture employs suspension- and modified bulk-polymerized PVC in processes requiring intensive mixing, dry blending, or calendering, and emulsion-polymerized resin in processes involving liquid coating of plastisols.

Stabilizers. As with any compounded poly(vinyl chloride) system, the flooring composition must be protected against degradation

from the effects of both heat and ultraviolet radiation during processing and during its service life. The stabilizers most commonly used in vinyl flooring are soaps of barium, calcium, and zinc, and certain organotin compounds. Lead and cadmium soaps have been used in the past but, although effective stabilizers, they are not widely used today because of environmental concerns and their tendency to form colored sulfides, a phenomenon referred to as sulfur staining). Epoxidized oils such as soybean oil, tallate esters, and other partially unsaturated oils are frequently used as costabilizers and secondary plasticizers in compounds stabilized with metallic soaps. Organophosphites are also frequently used as chelating agents and antioxidants in conjunction with metallic soap systems.

The particular blends of stabilizers used in flooring are proprietary to the manufacturers because of their subtle effects on other properties important to the production or performance of the products. An example of interaction is the accelerating effect by zinc soaps on the decomposition of the blowing agents used to expand the foamed layer in some vinyl flooring.

Plasticizers. The vinyl binder system in flooring is plasticized to provide flexibility and resilience, as well as to facilitate processing. Di(2-ethylhexyl) phthalate has been the most frequently used plasticizer for flooring because of its relatively low cost, permanence, color, and overall balance of performance properties. However, because of current controversy regarding long-term health effects of this plasticizer, it has been largely replaced in the United States by diisononyl, diisodecyl, and diisoheptyl phthalates.

Butylbenzyl phthalate, historically used for production of vinyl composition tile, is increasingly being used in plastisol coatings and foamable base. This is a very efficient, highly solvating plasticizer, and when used in plastisol coatings, viscosity-depressant plasticizers such as TXIB (2,2,4-trimethylpentane-1,3-diol diisobutyrate) and dodecylbenzene are frequently included [12].

Fillers and Pigments. With the exception of the clear wear layer in most residential and some commercial flooring structures, the stabilized and plasticized vinyl formulation, i.e., the binder, is mixed with varying amounts of inorganic filler to provide mass and thickness at a reasonable cost. Pigments are added to provide color, opacity, and design.

Calcium carbonate (limestone) is the filler of choice in flooring formulations because of its low cost, lack of color, and low plasticizer absorption properties [13]. Talc and clay are rarely used, because of their significant stiffening effect on plasticized vinyl. Asbestos was used in the past in vinyl asbestos and asphalt tiles, and some sheet flooring, but it is no longer used in flooring made in the United States.

Fillers provide not only bulk and mass at reasonable cost but also increased dimensional stability, opacity, resistance to cigarette burns, improved flame spread ratings, reduced smoke generation, and reduced memory and elasticity.

Pigments used in flooring must be heat stable, lightfast and resistant to change in color from alkaline moisture The preferred white pigment is titanium dioxide. Most colored pigments are inorganic, but certain colors, primarily the blues and greens and some yellows, are only available as organic compounds.

Other Compounding Ingredients. In many public facilities, flooring must meet certain code requirements with regard to fire and smoke properties. Specific additives may be used to reduce the flame spread and smoke generation of the products. Agents used for this purpose include alumina trihydrate, antimony trioxide, zinc oxide, boron compounds, phosphate esters, and chlorinated hydrocarbon plasticizers.

The foam layer in cushioned flooring is chemically expanded by the thermal decomposition of azobis(formamide) blowing agents. Some formulations may also contain processing aids and lubricants depending on specific processing methods and requirements.

2.3.2. Sheet Vinyl Flooring

Cushioned Rotovinyls. Cushioned rotovinyls are the most common form of sheet flooring on the market today and are used extensively in residential applications.

The structure (Fig. 7) typically consists of a backing of felt composition, glass scrim, or an

extensible vinyl film; a foam layer for cushioning and to facilitate pattern embossing; a rotogravure printed pattern, and a transparent or translucent unfilled vinyl wear layer.

Figure 7. Typical rotogravure sheet flooring structure
a) Felt composition backing; b) Foam interlayer; c) Rotogravure print; d) Clear wear layer

Production. The production of cushioned rotovinyls depends largely upon the use of vinyl plastisols in which emulsion-polymerized PVC, blending resins, pigments, stabilizers, and other additives are dispersed in the plasticizer system. When heated to approximately 180 – 200 °C the plasticizer(s) solvate the resins to form a tough plastic film. Typical formulations employed are shown in Table 1.

Table 1. Typical formulations for some vinyl flooring structures

Ingredients	Formulation∗, parts by weight per 100 parts resin				
	A	B	C	D	E
Vinyl resin(s)	100	100	100	100	100
Plasticizer(s)	30	60	30	35	40
Epoxidized oil	5	5	4	5	
Processing aid					8
Stabilizers	2.5	2	2	3	2
Fillers and pigments		30	210	70	640
Blowing agent		5			

∗ A = clear coat for rotogravure flooring; B = foam coat for rotogravure flooring; C = filled wear layer for inlaid vinyl flooring and vinyl tile; D = homogeneous sheet flooring; E = vinyl composition tile.

Rotovinyl sheet flooring is built up of several layers of plastisol coatings applied to the carrier by reverse-roll or knife-over-roll coating. The backing felt or other carrier is coated with a foamable plastisol containing the blowing agent [typically azobis(formamide)], which decomposes at elevated temperatures to create the expanding gases. In some structures a nonfoamable base coat may first be applied. After coating, the foamable plastisol is gelled (partially fused) at a temperature below the decomposition temperature of the blowing agent to form a smooth printable substrate (Fig. 8).

The gelled foam coat is then decorated with vinyl inks by direct or offset rotogravure printing to create the desired pattern. Registered embossing is usually achieved by incorporating agents in selected inks that interfere with the expansion of the foam coat [14]. There are also sophisticated systems for mechanically embossing in register.

A transparent or translucent plastisol is coated onto the printed gel coat, and the entire structure is heated to a temperature adequate for complete fusion of the plastisols and expansion of the foam layer to produce the final product. Some processes use mechanical embossing techniques to create overall textures in this final step.

Characteristics and Uses. The most common width of cushion rotovinyls is 12 feet, (3.66 m) although 6, 9, and 15 foot (1.83, 2.74, and 4.57 m) widths are also produced. The backings, foam, and wear layer are available in various gauges depending on the intended applications. The composition and thickness of the components are descrided in ASTM F 1303-97 [15]. The pattern design potential is virtually unlimited because of the versatility of rotogravure printing.

Cushion rotovinyl is today the most popular resilient flooring product in the residential market. Most products are promoted as not requiring waxing for normal use and many have surface coatings of polyurethane, urethane acrylate, or other proprietary cross-linking materials for improved stain resistance and sustained gloss retention. These coatings may be cured by ultraviolet light or conventional heat in the final stage of production.

The foam interlayer provides underfoot comfort and warmth. It is also fairly effective in reducing the transmission of impact sound from the floor to the space below, and combined with appropriate subfloor structures, can be used to achieve certain impact-isolation class requirements in multifamily housing units.

Inlaid Sheet Vinyl Flooring with Backing. Products in this category have a felt or filled vinyl backing with an inlaid vinyl wear layer of varying thickness, depending on intended end use [15]. The heavier gauges are used primarily for commercial and institutional applications (Fig. 9).

Figure 9. Typical inlaid vinyl sheet flooring structure
a) Felt composition backing; b) Filled vinyl composition; c) Unfilled vinyl matrix

Production. A typical formulation for the filled component of the wear layer is shown in Table 1, column C. The resins used are primarily suspension PVC homopolymer, but some copolymer may be used in accent colors to control graining. The primary plasticizers are generally of the phthalate type, although some products may contain phosphates and/or chlorinated hydrocarbons to improve flammability ratings. The filler is usually calcium carbonate.

The ingredients are mixed and fused in a high-intensity mixer or a reciprocating screw extruder and milled and/or calendered into sheets of plain or variegated color. These are then fractured, cut, or ground into various shapes and sizes depending on the finished design requirements. Different colors of particles are frequently combined to produce a mottled mix. To produce random inlaid design the particles are cast onto the backing and fused and consolidated by heat and pressure, with or without an unfilled vinyl matrix surround, in flat-bed or rolling presses. Deliberate imitative designs may be achieved by using a stenciling operation to position granulated color onto the carrier to produce a specific pattern.

Characteristics and Uses. Inlaid sheet vinyl flooring is normally supplied in widths of 6 – 6.5 feet (1.8 – 2 meters). The inlaid construction of these products makes them sturdy and durable. Their more massive wear layer, supported directly by the felt or filled vinyl backing, provides resistance to damage by cuts and punctures and thus makes them suitable for commercial applications.

These products have found widespread use in health-care facilities, schools, and institutions. They are used also in abusive residential applications such as dormitories and military housing.

Homogeneous Sheet Vinyl Flooring. These products may also be referred to as solid vinyl sheet flooring or PVC sheet flooring. They have been popular in Europe for many years, particularly for commercial and institutional

applications, and since the 1980s have found increased popularity in the United States.

Production. Homogeneous vinyl sheet flooring is normally manufactured by a combination of calendering, consolidating, and/or laminating processes. A generalized formulation is provided in Table 1, column D. The types of resins, plasticizers, stabilizers, and fillers are similar to those discussed under inlaid vinyl flooring.

The compounding ingredients are mixed and fused in a high-intensity, high-shear mixer, (Fig. 10 A, e) and sheeted through one or more two roll mills (f, g). Previously prepared accent colors are added to the web at one of the mill nips to produce sheets with the desired graining. The material is then calendered through a four-roll calender (i). If the resulting sheets are to be built up to achieve the required finished gauge, they may be laminated together in a continuous or intermittent pressing operation to obtain the desired thickness (Fig.10).

Characteristics and Uses. These floors are produced primarily as roll goods, but some manufacturers cut the stock into sheets, usually three feet (0.9 m) square, or into one foot square (0.3 m) tiles. Roll widths vary from four feet (1.22 m) to 6.5 feet (2 m). The most frequently specified thickness for commercial applications is 80 mil (2 mm), although 60 mil (1.5 mm) gauge is also produced by some manufacturers. Depending on the structure and process employed in production, the pattern and graining is fairly consistent throughout the thickness of the product. Some laminated structures, while being of solid vinyl construction, may have the pattern only in the top layer. Their construction and performance requirements are described in ASTM F 1913-98 [16].

This is the most durable type of vinyl flooring available today. It is formulated with fairly high molecular mass homopolymers and contains relatively little inert filler. This, combined with its thickness and through-color construction, results in excellent resistance to abrasion and other mechanical damage from punctures, cuts, and gouges. Its composition also provides good chemical resistance.

Because of these factors and the fact that this flooring is installed with heat-welded seams, it is used in commercial and institutional areas having rigorous performance requirements such as industrial, medical, and educational laboratories, and clean rooms; veterinary clinics; outpatient health care clinics; and in hospital procedure rooms, including surgeries.

Layered Composite Flooring (Heterogeneous Sheet Flooring). Versions of solid vinyl flooring becoming increasingly popular in the United States are composite structures having a clear wear layer of at least 20 mils (0.5 mm) in thickness over a printed pattern on a filled vinyl backing. The product may or may not be reinforced with glass scrim.

The compounding ingredients are similar to those mentioned for both residential rotovinyls and homogeneous vinyl sheet flooring. In those cases where the wear layers are produced by hot-melt calendering, no viscosity reducing plasticizers are necessary. The products are produced by a combination of calendering the individual layers, plastisol coating or saturating the fiber glass reinforcement, if employed, and laminating in a continuous belt laminator (Fig. 10 B).

2.3.3. Tile Flooring

Vinyl Composition Tile. (VCT) is the most widely used resilient tile product today. Because of the general concern over the use of asbestos, it has superseded vinyl asbestos tile (VAT).

Production. A typical formulation for VCT is shown in Table 1, column E. The vinyl resins normally used in VCT are vinyl chloride – vinyl acetate copolymers having a vinyl acetate content in the 6 – 13 % range. The copolymers may also be blended with PVC homopolymer to achieve certain processing characteristics. Processing aids, typically low-melting hydrocarbon resins, are used to lower the fusion temperature and to assist in the mixing process.

The plasticizer system consists of varying blends of dihexyl phthalate, diisoheptyl phthalate, diisononyl phthalate, and butylbenzyl phthalate. Epoxidized soy oil is also commonly used as a coplasticizer/stabilizer. Manufacturers carefully guard their actual formulations, particularly with regard to fillers and stabilizers because of their subtle, yet important effect on performance properties.

The ingredients are combined in a high-power, high-shear, heated mixer, (Fig. 11 a) such as a Banbury mixer to blend and fuse the in-

gredients together. A heavy doughlike mass is formed and dropped from the mixer onto a two-roll mill (c). Accent colors (b), of the same or similar composition are added to the mill nip in the manufacture of grained or jaspé sheet.

When the mixing is complete and the graining judged right, the stock is cut (doctored) off the mill roll and folded into blankets to create more uniform graining when passed through the sheeting calender (f). The continuous web exiting from the sheeting calender is passed through a second finishing calender (h) to reduce it to the final gauge and provide a smooth face. For the production of tile having a surface applied design, previously prepared accent chips are applied (g) to the face of the tile between the first and second calender. Through-grained tile may also be produced by casting pre milled and fractured color chips onto a carrier belt, heating in an oven or by radiant heater, and consolidating in the sheeting calender (f). Tile having an embossed surface texture is embossed by passage between another pair of rolls (i) with tooled embossing on the top roll.

After exiting the finishing calender or, if used, the embosser, a factory finish of wax or synthetic polish may be applied (j) to the hot sheet to provide uniform gloss, and prevent blocking of the tile in storage. The sheet is then cooled (k) and die-cut in a punch press (m) to the finished size. The cut tiles are then inspected and packed (n). Rejected tile and frame scrap from the punching operation is recycled (o) to the mixer.

Characteristics and Uses. Vinyl composition tile is produced in several gauges, sizes, and styles for differing intended end uses. For residential applications, VCT is offered in service gauge, which is approximately 1/16 of an

inch (ca 1.5 mm) thick. These tiles are frequently embossed and may contain surface applied patterns and grainings. Most residential tiles today have a printed decorative pattern with a clear vinyl wear layer laminated to a solid color vinyl composition tile backing and embossed in register. Many also have high-performance no-wax finishes, as described for sheet flooring (Section 2.3.2).

Most commercial tile is 1/8 of an inch (3.2 mm) thick, however 3/32-inch (2.4-mm) tile is also available for use in light commercial applications. Tile for commercial applications is usually of the through-grained variety rather than surface applied designs. The standard size of VCT is 12 × 12 inch (305 mm square), but other custom sizes may be available.

In the manufacture of vinyl composition tile, particular attention is given to the dimensional stability, size, squareness, and the quality of the edge cutting. These qualities are essential for successful installation of the tile floor. Structure and performance requirements of VCT are contained in ASTM F 1066-95a [17].

Vinyl composition tile is considered to be the standard or base-grade commercial finish flooring. It has the lowest relative installed cost and has established a good performance record for this use. The major outlet today is the mercantile market. It is used almost exclusively for the general floor area of grocery stores, supermarkets, and discount department stores. It is also used extensively in schools, health-care facilities, and to a lesser extent in offices, banks, and light industry.

Vinyl Tile. Vinyl tile may be referred to as "solid vinyl tile", "homogeneous vinyl tile" and even erroneously, "pure vinyl tile". The primary difference between vinyl composition tile (VCT) and vinyl tile is the binder content. Vinyl tile generally has a binder content in excess of 34 % of the formula weight [18]. There is no minimum binder content requirement for vinyl composition tile.

Production. The formulation of solid vinyl tile is very similar to that used for the filled component of inlaid sheet flooring or some homogeneous flooring. See Table 1, column C for a typical formulation.

Since there are many proprietary methods used for the production of vinyl tiles it is not possible to describe a specific manufacturing process here. In many respects the processes are similar to those used in the production of homogeneous sheet vinyl flooring (see page 17)

Characteristics and Uses. Vinyl tile is more varied in construction than is vinyl composition tile. Appliqué tiles consist of two distinct layers, a base layer in one color and a overlay cut to resemble brick or other pavers. Other styles have through-grained marble or mottle designs, while still others are solid-color pavers. The overall thickness is usually 1/8 inch and it is available in both 9 × 9 inch (0.2 m) and in 12 × 12 inch (0.3m) sizes.

Vinyl tile is considerably more flexible than vinyl composition tile and has different specification requirements, particularly with regard to recovery from indentation and flexibility. Because of its high binder content it has significantly higher resistance to abrasive wear and is more resistant to impact damage. Conversely, its higher binder content makes it less resistant to damage from accidental cigarette burns.

The initial cost of vinyl tile is significantly higher than VCT, but because of its flexibility, resilience, and high degree of abrasion resistance, this product is very suitable for areas subjected to high pedestrian and cart traffic. Many vinyl tiles are offered in imitative patterns of brick, slate, and ceramic pavers and are frequently used in mercantile settings to highlight special merchandising areas in the store.

2.4. Rubber Tile and Sheet

Rubber tile and sheet flooring was introduced in the 1920s and was widely used through the 1950s, particularly for applications unsuited to linoleum and asphalt tile. Its popularity declined through the 1960s and 1970s because of the relative success of vinyl tiles and sheet flooring. In the mid-1980s it made a comeback in certain specific applications, due partly to the popularity of the raised-disk design used for slip retardance in areas of heavy pedestrian traffic.

Production. Modern rubber flooring uses styrene – butadiene rubber (SBR) as the primary binder. Other rubbers that may be incorporated with the SBR include Neoprene and nitrile rubbers as well as ethylene propylene diene

monomer elastomers (EPDM). A typical rubber flooring formulation contains the rubber or rubber blend, a high-styrene resin as hardener, perhaps a hydrocarbon oil extender, fillers and pigments, and vulcanizing agents such as sulfur and zinc oxide. The preferred fillers for rubber flooring are clays and talcs because of their reinforcing nature. Limestone whiting may be used as an extender in some compounds.

The ingredients are blended typically in a Banbury mixer, followed by sheeting through a two-roll mill. The sheet from the mill, along with previously compounded accent colors is rolled into a "pig" that is fed to a four-roll calender; there, the accent colors produce the marbleized graining, and a relatively smooth sheet approaching the final gauge of the product is prepared.

For the manufacture of tile and nonroll goods, this sheet is cut into slabs that are press cured at elevated temperature for 10 – 12 min in multiple or stack presses. Roll goods are cured in a continuous press such as a Rotopress.

After curing, the material is allowed to age a day or two before cutting to the finished size. The back of the tile may be sanded or have embossed ribbing to provide better grab of the installation adhesive.

The wearing surface may be smooth or may have a molded embossing such as round disks, raised squares, or other configurations to furnish slip-retarding characteristics and provide special design effects.

Characteristics and Uses. Rubber flooring is very durable, with excellent resistance to abrasion, recovery from indentation, quietness under foot, and the best resistance to accidental cigarette burns of all the modern resilient flooring products. It also has better resistance to polar organic solvents, such as acetone and other ketones, esters, and cyclic ethers. However, it has poorer resistance to aliphatic and aromatic hydrocarbons and vegetable oils than do vinyl products.

Rubber flooring is frequently specified in light industry and laboratories, where its unique solvent resistance is required. It is also used in health-care facilities and schools, where its good wear resistance and resilience are needed. Raised-disk rubber flooring has found widespread acceptance in areas where wet slip resistance is required or where that particular decorative effect is desired.

Rubber flooring composition is also used extensively for molded stair tread, risers, and landings in public stair ways.

2.5. Specialty Flooring Products

Conductive flooring is used in areas where explosive or flammable vapors or dusts may exist, or where control of static electricity for sensitive electronic equipment is needed. These products obtain their conductivity by the use of conductive carbon black in the formulation which somewhat limits the color and design capabilities. Conductive flooring is manufactured to meet the requirements of the National Fire Protection Association (NFPA) for explosive or flammable environments [19].

Static-Dissapative Flooring. For the control of static electricity for electronics applications, flooring products are available that are less conductive than conductive flooring. The resistance to ground need only be in the range of 10^6 to 10^9 ohms, which can be achieved by incorporating quaternary ammonium compounds in the formulation.

Slip-retarding flooring is used on ramps or in areas where the floor will be subject to frequent wetting such as entryways, vestibules, food-preparation areas, etc. This flooring may have raised areas or deep embossing to help prevent hydroplaning when wet; alternatively, mineral particles such as carborundum, quartz, or other mineral aggregates may be incorporated in the surface to provide increased friction with shoe soling. Combinations of these two configurations may also be used.

3. Laminate Flooring

For some years high-precision manufacturing methods have been available for the production of flooring elements that can be laid – mainly as floating floors – with surfaces ready to be walked on. These can be products with wood surfaces (parquet flooring) or laminated elements.

A distinction is made between flooring elements that are laminated during manufacture and those which are combined with laminated materials [high-pressure laminate (HPL) or continuous pressed laminate (CPL)] in a separate operation. The former are produced exclusively on high-density fiberboard (HDF) substrates, whereas particleboard can also be used for the latter. Because nowadays very thin decorative laminate sheets can be produced, these are often indistinguishable from films.

3.1. Development

The first laminated floors were produced by Perstorp in Sweden in the 1970s. This major manufacturer of decorative laminates uses only materials produced in its own factory, which are applied by the short-cycle pressing technique to particleboard. For many years, Perstorp was the only commercial manufacturer. Then, as rumours grew of allergic reactions to textile floor coverings, wood-based materials, whose health credentials were unquestioned, became more important.

Figure 11. Construction of a laminate flooring tile (Witex) a) Very hard resin coating; b) Tongue-and-groove joint with extra impregnation to give water resistance; c) HDF substrate; d) Resinized patterned film, e.g. ,with the appearance of wood or stone, stable to UV light; e) High-strength film for extra hardness and impact resistance; f) Resinized protective film affords dimensional stability

After many years of rapid market growth and healthy profits, there is now stagnation and considerable continuing growth in production capacities. Meanwhile, laminated flooring elements are sold by large building suppliers at prices below 10 DM/m^3. Stable market development will be assured not only by favorable prices, but also by products that are suitable for do-it-yourself floor laying.

3.2. Construction

The construction of laminated flooring elements is very simple. To the bottom of the HDF substrate is applied the protective film, and to the top of the substrate are applied either the patterned film alone, the patterned film plus the overlay, or the underlay plus the patterned film plus the overlay (Fig. 11).

3.3. Materials

The substrate is the load-carrying element of the design. It must be as dense and hard as possible to resist loading pressures from furnishings. Recently, melamine-resin-bonded HDF has been used for high-quality products because of its considerably better resistance to moisture relative to urea-resin-bonded products. The underlying protective film increases the stability of the element, ensures constructional symmetry, and prevents the ingress of moisture from below. An underlay prevents the often dark background color of the substrate from showing through light-colored patterned films and reinforces the whole assembly against high-pressure loads.

The main function of the patterned film is decorative. It also has a load-bearing function and is responsible for the wear-resistance properties if it is not covered by an overlay. In the former case, it is resin-treated in two stages, first by conventional impregnation and then, after a short intermediate drying stage, with an additional melamine resin layer.

The overlay consists of carrier papers of pure α-cellulose containing micronized corundum powder, which is added during the production process. These special papers are patented and are produced in the United States. They enabled high-quality laminated flooring elements to be manufactured for the first time.

3.4. Production and Installation

Pressing. Hydraulic presses are the principal machines used in the manufacturing process, and these are also used in the production of self-supporting decorative laminated plates, for which all three types of commonly used presses are used: multiplate presses with cooling, one-plate presses without cooling, and double-band presses with or without cooling. Direct lamination is by far the most important process in the manufacture of flooring elements, mainly by short-cycle pressing. However, some double-band presses have been installed recently.

In *short-cycle pressing*, pressing times of 10 – 20 s (depending on the number of films to be applied) and pressures of 3 MPa are normally used. Up to two cycles per minute at pressing temperatures of 180 °C are currently achieved. The following operations are performed fully automatically:

- From height-adjustable holding racks, usually with three compartments, film is withdrawn by pulling devices. When the protective film is in position, the substrate is offered up to it by means of a movable arm with suction pick-up, and the film is applied from above in a second station. The film is applied as precisely as possible to minimize film overlap and reduce formation of waste by splintering. For flooring elements, especially with patterned strip flooring, the symmetry of the pattern across the width is very important. The printed areas at the joints must be in exact alignment.
- The short-cycle presses of various machine manufacturers differ only in their feed systems, whereby speed is of the greatest importance. Here, the critical dwell time, which begins with the application of heat in the compression space and ends when sufficient pressure is reached, plays an important role. It is ca. 2 s. Such short times can only be achieved with the aid of equipment that alternately feeds materials and discharges the tiles at high speed.
- The final operations are to clean the edges of the tiles, to check the surfaces visually, and in some cases to cut the tiles and stack them.

Changing the pressing plates plays a very important role in short-cycle pressing technology, as the stainless steel pressing plates also act as embossing matrices. A rapid changeover gives great flexibility in the short-cycle pressing process. The plate-changing operation is therefore also automated. The equipment for this purpose has access to a compartmented magazine that normally stores 15 different matrices. The changeover cycle requires only 10 min. It is operated by a movable arm, which uses suction to pick up the plate that has been taken out of the compression space by the discharge equipment and places it on the band conveyor which takes it to the plate magazine. After the old plate has been placed in the magazine, a new plate is taken out by reversing the process.

There are two fundamentally different *double-band pressing* systems in competition with each other. One operates with a surrounding sealed cushion of compressed air, and the other with free-flowing oil films on which the stainless steel bands slide. For coating operations with relatively simple process parameters, the much cheaper version with the air cushion can be considered, while for high-pressure coating materials the other system is recommended because of its ability to meet demanding requirements.

Double-band presses are now available in every working width demanded today. In contrast to the short-cycle pressing technique, in which the films are seldom fed from rolls, double-band presses are always supplied from rolls of film. This is one of the advantages of continuous pressing. Film storage and feeding mechanisms occupy very much less space than is required in short-cycle pressing technology. As flooring products are produced in large quantities, the rolls of film can be used continuously without interruption, and the management of left-over materials on rolls is minimized.

The process parameters are approximately the same as those in short-cycle pressing technology. The feeding rate, which determines the production capacity, is ca. 18 m/min. Assuming a heated film length of 2000 mm, this would give a pressing time of ca. 6.5 s. This extremely short pressing time can only be realized if the films are impregnated in-house with adherence to strict conditions. These include the quality and age of the resin for the impregnation process and also the storage time of the impregnated films. The film resins must have sufficient time under pressure to enable them to flow. Only then can the required fully densified surfaces be achieved.

Production capacity is an important criterion for choosing between short-cycle and double-band pressing. Thanks to the continuous improvements being made to digital servo-motors and other control systems, the speed of the short-cycle pressing technique is continually being increased, so that charging times play a continually diminishing role. Thus, it was only a question of time until the 18 m/min or even 20 m/min of the double-band presses could be matched by long short-cycle presses, albeit at the cost of increased space requirements. A major press manufacturer in Westphalia has delivered a short-cycle press of 13 m operating length to Italy. It is expected to operate at two cycles per minute. Double-band technology will respond with an extended compression area. However, as the hardening reaction takes place essentially over the first meter, this imposes strict demands.

Embossed pressing bands are much more expensive than the equivalent pressing plates. Also, changing the pressing band is much more time-consuming and difficult. However, flooring elements without embossing are of lower quality, both visually and for practical purposes. The wide range of embossing patterns that can be produced by pressing plates is not available with bands, simply because of the exorbitant costs of the latter. However, the continuous process achievable by continuous presses gives considerable potential savings in the consumption of electrical and thermal energy.

Conditioning and Cutting. After pressing, the laminated plates are allowed to stand so that internal stresses caused by unevenly distributed moisture and temperatures can even out. Short-cycle products are generally stacked for about 5 d. Attempts are being made to shorten this time by using star coolers. Double-band presses with cooling give products that are much easier to cut and which only require about half the time for stress relief.

After conditioning of the full-sized products, they are precisely cut to the required dimensions. Patterned products have a clearly visible symmetry line that was applied applied during pressing. Prior to the multibladed saws, alignment devices adjust the position of the sheet until two optical sensors indicate that the symmetry axis has been reached.

Two types of multibladed saws are used. One operates with a single motor which drives a central, replaceable drive shaft to which the saws are attached, usually by quick-release bushes; the other has a drive for each saw blade, and these can be rapidly adjusted to different widths by digital controllers. Inoperative motors are stored in parking stations. Depending on the format of the sheets, lengthwise cutting can precede several transverse cuts. The cut products are conditioned for up to two more days to relieve the stresses that are an inevitable consequence of the cutting process.

Formatting and Profiling. Variants of the above process all aim to reduce the conditioning time. These include direct linking of the cutting saw with the profiling production line. In all cases, this involves risks. Whether these outweigh the gain in rationalization is a question that must be considered. After cutting, the workpieces always lie with the patterned side upwards. On placing the tiles in the profiling line, the patterned sides are turned to face downwards so that the underside of the element is subject to the tolerances of the profiling step.

Profiling is performed by two angled double-ended profilers. The first, for the lengthways machining, can be replaced by a grooving machine. Modern production lines have high outputs. The newest plant can produce 120 elements per minute, sort them, pack them into cartons, stack the cartons on palettes, and load the palettes into containers.

The design of the milling stations is decisive for the fit of the profiles. An absolutely level surface of the fitted flooring, with gap-free joints both lengthwise and crosswise, is the criterion by which the customer will eventually judge the quality. A precisely level surface can only be achieved if the workpieces are milled to give a close fit one with another over the entire batch. With high feed rates, there can be undesired frictional heating, which can be aleviated by a carefully controlled air cushion. The profiles must not only mate cleanly, but above all must show high repeatability. From one consignment to the next, year after year, there must be no flaws of any kind.

The sharpness and life of the tools play an important role. Overlays filled with corundum powder lead to tool wear because of their very

abrasive properties. Hence, only diamond tools are used, and these are replaced at high speed with the aid of a quick-action chuck. Polycrystalline and monocrystalline diamond fragments (PCD and MCD, respectively) are under discussion for this application. It would appear that the extremely expensive MCD tools are not cost-effective, although their useful life is many times that of PCD tools.

Water-Resistant Finishing. As it is not yet standard to use melamine-bonded HDF as substrate, the profiles are impregnated with water-resistant material after both lengthwise and crosswise machining. The water-repellent material is applied evenly over the whole length of the joint without allowing it to spread over the surface; it is then allowed to soak in and dry. The water-resistant material must not affect the adherent properties of the adhesive used for the installation of the floor.

Packaging. A quantity of floor tiles equivalent to approximately 2 m^2 of flooring has become established as a suitable package size. Packaging is carried out in the profiling production line, and is therefore subject to demands for high production rates. Few manufacturers use completely automatic packing equipment. The cheapest method is to secure the packages, which usually contain eight flooring elements, with sealing tape. These, together with the product information, which is also automatically packed, are then shrink-wrapped to give protection from dirt and moisture. Packing in cartons gives greater protection against damage. The elements can either be placed, from above, in an automatically prefolded carton or be packed in a slip-lid carton. Here, too, additional foil wrapping is advisable. The product information and preferably also the patterned surface should always be visible from outside, for example, through a window.

Installation. Laminate flooring is laid by floating on sheeting that deadens impact sound and protects from moisture (Fig. 12). In accordance with the guidelines for laying PVC flooring, the base, usually concrete, must be well dried and even, as these thin flooring materials are not capable of bridging over large discontinuities.

Figure 12. Laying of laminate flooring
a) Laminate flooring; b) Wool-felt board; c) Vapor barrier; d) Flooring plaster; e) Heating tube; f) Screening; g) Insulation; h) Moisture barrier; i) Concrete floor

The floated surface forms a large unit with material-corresponding shrinkage or growing, and water imbibition values. It must therefore always be kept at a distance of at least 10 mm from walls and pillars, and these gaps can be covered with matching edge strips. Both adhesive and mechanical fixing of flooring elements are used. The former still dominates the market, but will probably be replaced by dry methods. The poly(vinyl acetate) adhesive must exude upwards through the joints along their entire length to prevent water penetration. With mechanically fixed elements, this additional protection is not provided, and a water-resistant finish or water-resistant substrate is necessary. The fixing adhesives must be moisture-proof, tough, elastic, and of high strength.

3.5. Testing

Laminate flooring was defined in early 2000 in the European Standard EN 13 329 and its specifications and properties were described. Laminate flooring is described as having closed pores, and this property can be measured by testing its sensitivity to staining by certain test materials (e.g., graphite). According to EN 438, laminate flooring is Grade 3, but it should preferably be Grade 4.

Before the appearance of the laminate flooring standard EN 13 329, the abrasion resistance was determined and used as a single value in accordance with EN 438. Because of the unsuitability of the testing of highly wear-resistant

Table 2. Abrasion resistance classes for laminate flooring

	Level of use					
	Domestic			Commercial		
	Moderate	General	Heavy	Moderate	General	Heavy
Class	21	22	23	31	32	33
Abrasion resistance	AC1	AC2	AC3	AC3	AC4	AC5

laminate flooring by methods developed for furniture, values of 4000 – 20 000 revolutions were quoted as test results. In the new standard the wear resistance test has been improved, and the test for highly wear resistant overlays has been modified.

The new test results enable the products to be grouped according to their abrasion resistance, so that each type of overlay can be assigned to an abrasion-resistance class (Table 2).

The well-known hardness tests such as Brinell and ball indentation values are of only limited suitability for determining the hardness of a laminate floor. These tests therefore do not feature in the European laminate standard. The French laminate standard NFB 54 020 gives a minimum value of 4 or 5 MPa.

Laminate floors are produced with a wide range of gloss values. Two or three years ago these were in the 10 – 15 range, but now more and more producers offer gloss values of 18 – 20. These high values enable reproduction to be even more realistic.

As a result of overlay technology and the existence of melamine resins, laminate floorings are very resistant to heat and are therefore resistant to a glowing cigarette (better than Grade 4 of EN 438). As a rule, laminate floorings meet the requirements of B1 of DIN 4102 Part 14.

Taking all their properties into consideration, laminate floorings stand up very well in comparison to other floor coverings. Past criticisms with respect to moisture sensitivity and footstep noise are to be set against the developments in modern laminate floorings. Special backing coatings and nonswelling substrates are reducing footstep noise and improving edge instability.

Whereas attempts are still being made to develop a scientific test for footstep noise, testing methods for edge-swelling behavior and the measurement of dimensional stability by modified testing procedures are described in EN 13329, maximum edge-swelling values being 18 % for commercial and 20 % for domestic use.

Other test specifications of relevance for laminated floorings are listed below:

EN 309	Wood Particleboards – Definition and Classification
EN 311	Particleboards – Surface Soundness of Particleboards – Test Method
EN 316	Wood Fibreboards – Definition, Classification and Symbols
EN 318	Fibreboards – Determination of Dimensional Changes Associated with Changes in Relative Humidity
EN 438	Decorative High Pressure Laminates (HPL) – Sheets Based on Thermosetting Resins
EN 685	Resilient Floor Coverings – Classification
EN 12529: 1998	Castors and Wheels – Castors for Furniture – Castors for Swivel Chairs – Requirements

3.6. Environmental Aspects

Laminate floorings are built up of layers of various materials. This often leads to the assumption that "plastic floor coverings" are difficult to dispose of in an environmentally friendly manner. However, laminate floorings can be disposed of like furniture and with as few problems. In both cases, because of the high wood content, the most appropriate disposal route is controlled combustion, the heating values being good.

VOC emissions from the product are very low, so that a laminate floor is classified as a very low emission material. Formaldehyde emissions are in the range 0.02 – 0.04 ppm, i.e., on the order of those of natural wood.

Milling operations produce wood dust and shavings. The usual national recommendations apply to these materials. When the material is cut during the course of installation on a building site, dust emissions can vary. Saws should preferably be provided with dust-extraction equipment.

Figure 13. European sales (including exports) of laminate flooring (in 10^6 m^2)

3.7. Economic Aspects

The European market for laminate floorings continues to grow rapidly and is forecast to be 180×10^6 m^2 in the year 2000 (Fig. 13, while the German market is expected to level out at ca. 40×10^6 m^2. In western Europe, laminate flooring had a ca. 6.8 % share of the total flooring market in 1998, corresponding to ca. 100×10^6 m^2.

1. Introduction

Fluorescent dyes differ from normal dyes in that they produce exceptionally bright colors because they not only absorb light, but also emit it. Fluorescent dyes are used mainly as disperse or reactive dyes (→ Disperse Dyes, → Reactive Dyes) in the coloring of textile fibers and plastics, in the production of inks and printing inks and, in combination with appropriate pigments, in the production of paints and lacquers. Fluorescent dyes are also employed as laser dyes (→ Laser Dyes). Furthermore, daylight fluorescent dyes may be dissolved in a resin matrix and then pulverized to form fluorescent pigments (see Chap. 12).

Fluorescence occurs when molecules that have absorbed light and are in their lowest excited state S_1 return to their ground state S_0 and emit light (for a detailed discussion of fluorescence, see → Dyes, General Survey, Chap. 2.4.). Some of the absorbed light energy also activates nuclear vibrations and is released as heat. Further energy is lost due to the conversion of the lowest excited state S_1 to a triplet state T_1 (*intersystem crossing*) and is not available for fluorescence. The *quantum yield* is a measure of the fluorescent efficiency of a compound, i.e., the proportion of the absorbed light energy that is emitted as fluorescent light.

Fluorescent dyes absorb and emit light in the visible region of the spectrum. The fluorescent dyes treated in this article are distinguished from optical or fluorescent brighteners (→ Optical Brighteners), which absorb in the invisible UV region and emit blue to blue-violet light.

Fluorescent dyes usually have extremely rigid, extended π-systems. Rigidity is of importance because it suppresses the release of energy due to activated nuclear vibrations. Substituents such as heavy atoms (chlorine and bromine) or nitro groups are detrimental to fluorescence because they favor intersystem crossing.

Many dyes exhibit fluorescence, but to be of practical use, fluorescent dyes must satisfy certain requirements: they must produce a pure color dictated by their absorption and emission spectra, they must have a high molar extinction, and most important, they must have a high quantum yield. These requirements are met by very few dyes. A disadvantage shared by many fluorescent dyes is their poor lightfastness, but there are some exceptions.

In this article some of the most important fluorescent dyes and their applications are described. For a general discussion of the properties of organic dyes and pigments, see → Dyes, General Survey; → Pigments, Organic.

2. Naphthalimide Dyes

A very wide variety of naphthalimide dyes are known (→ Naphthalimide Dyes and Pigments).

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a11_279

Only a few important representative examples, which show exceptionally brilliant, greenish-yellow fluorescent colors, are discussed in this section; they all show poor lightfastness. Brilliant Sulfoflavin FF (**1**),C.I. 56205 [*2391-30-2*] serves as a dye for wool and polyamides [6]. Solvent Yellow 44 (**2**),C.I. 56290 [*2478-20-8*] is used to dye plastics and is of some importance in the production of fluorescent pigments [7].

Compound **1** is prepared from *p*-toluidine and 4-amino-3-sulfo-1,8-naphthalic anhydride [*52173-68-9*] which is obtained by sulfonating 4-amino-1,8-naphthalic anhydride. The production of (**2**) involves the reaction of 4-chloro-1,8-naphthalic anhydride with *m*-xylidine, followed by the use of ammonia to substitute the chlorine atom with an amino group.

1

2

3

4-Amino-3-sulfo-1,8-naphthalimide is being increasingly used to dye wool and *N*-methyl(4-methylamino)-3-sulfo-1,8-naphthalimide [*54229-25-3*] to dye polyamides. Compound **3** [*23741-82-4*] is a reactive dye which is employed to dye cellulose fibers [8].

3. Coumarin Dyes

Dyes derived from coumarin, 2*H*-1-benzopyran-2-one [*91-64-5*], are usually intensely colored, brilliant greenish-yellow dyes with high quantum yields and high molar extinctions. They are moderately lightfast.

The most important fluorescent coumarin dyes are derivatives of 7-dialkylaminocoumarin, which has a heterocyclic residue at the 3-position (**4**).

4

R = alkyl

Fluorescent coumarin dyes are used as disperse dyes for polyesters and polyamides, their sulfonic acid derivatives are employed for dyeing polyamides, and their cationic derivatives are used for dyeing polyacrylonitriles. Some of these dyes are important as laser dyes or are used in the production of fluorescent pigments (see Chap. 12).

Coumarin dyes are obtained by reacting 2-hydroxy-4-dialkylaminobenzaldehyde with the nitrile (or acetate) derivative of a heterocycle as in the following example:

5

The use of a nitrile derivative results in the introduction of an imino group at the 2-position of the coumarin ring, as in compound **5**. Hydrolysis occurs under the conditions employed for dyeing, and the imino group is replaced by oxygen, yielding the corresponding coumarin derivative.

Some important 7-diethylcoumarin dyes (compounds **6**–**13**) are listed in Table 1. The introduction of a nitrile group at the 4-position of the coumarin residue gives the dye a red color, as in compound **14** [*70546-25-7*], which is the 4-nitrile derivative of **9** [15].

14

Table 1. 7-Diethylcoumarin dyes [9], [10], [11], [12], [13], [14]

Constitution of dye  R =	CAS registry number	Color	Use	Reference
6	[*27425-55-4*]	yellow	disperse dye	[a]
 **7**	[*12221-86-2*] (C.I. Basic Yellow 40)	yellow	for dyeing polyacrylonitrile, fluorescent pigment	[a]
8	[*38215-36-0*]	yellow	disperse dye, laser dye	[a]
 **9**		yellow	for dyeing polyamide	[b]
 **10**	[*34564-13-1*]	yellow	disperse dye	[c]
 **11**	[*62143-26-4*]	yellow	disperse dye	[d]
 **12**	[*28754-28-1*]	yellow	disperse dye	[e]
 **13**	[*55470-53-6*]	orange	for dyeing polyacrylonitrile	[f]

Compound **14** is used as a disperse dye for polyesters and produces a brilliant red color of moderate lightfastness.

4. Xanthene Dyes

Fluorescein (**15**), C.I. 45350 Acid Yellow 73 [*518-47-8*] is the best known xanthene dye (→ Triarylmethane and Diarylmethane Dyes).

15

Even a very dilute solution of this dye exhibits an intense yellowish-green fluorescence. It is synthesized by reacting phthalic anhydride with resorcinol. The eosines (bromine compounds) and erythrosines (iodine compounds), phloxine

B, C.I. 45410 [*18472-87-2*], and Rose Bengal, C.I. 45440 [*632-68-8*] are halogenated derivatives of fluorescein.

Rhodamine dyes (aminoxanthenes) are a very important class of xanthene dyes and are of considerable commercial importance. They are intensely brilliant, blue-red, fluorescent dyes with very high molar extinctions and quantum yields and are used for coloring inks, paper, and plastics. Their sulfonated derivatives are used to dye wool and polyamides. Rhodamine dyes are also the starting materials for the production of red fluorescent pigments; some of them are employed as laser dyes. The most important rhodamine dyes are synthesized by reacting 3-dialkylaminophenols with phthalic anhydride. The carboxyl group of the product may then be esterified.

The first of the rhodamine compounds to be reported was Rhodamine B (**16**), C.I. 45170 Basic Violet 10 [*81-88-9*] [16], which is used in fluorescent pigments.

16

Rhodamine 3 B (the ethyl ester of Rhodamine B), C.I. 45175 Basic Violet II [*2390-63-8*], and Rhodamine 6 G (**17**), C.I. 45160 Basic Red 1 [*989-38-8*], have properties similar to those of **16** [17].

17

The product of the reaction of 3-diethylaminophenol with benzaldehyde-2,4-disulfonic acid is Sulforhodamine B (**18**), C.I. 45100 Acid Red 52 [*3520-42-1*] [18], which is used to dye wool and polyamides. It is also employed in the production of fluorescent pigments, and as a laser dye.

18

The alkyl groups on the nitrogen atoms of Sulforhodamine 101 (**19**) [*60311-02-6*] are less flexible than those of Sulforhodamine B (**18**) [19], and the molecule is thus more rigid. Dyes of this type have very high quantum yields, approaching 100 %, and are used as laser dyes.

19

Compound **20** is used as a reactive dye for dyeing cellulose fibers [20].

20

The reaction of a coumarin dye with dicyanomethane produces compound **21**, which can be considered as an azaxanthene dye [21].

21

21a [*52372-39-1*]: X = NH
Hydrolysis of **21a** gives **21b** [*52372-36-8*]: X = O

This compound is used as a disperse dye for polyesters. It produces an intensely brilliant, moderately lightfast, red color.

5. Thioxanthene Dyes

The color of fluorescent thioxanthene dyes ranges from yellow to red. These dyes are usually less brilliant than the coumarin dyes and the rhodamines, but some of them show good lightfastness. The thioxanthene ring system is produced by means of a Pschorr ring closure, as shown for Fluorescent Red GG (**22**), C.I. Solvent Orange 63 [*16294-75-0*] [22]:

Plastics can be colored red with compound **22** which has a good lightfastness.

Samaron Brilliant Yellow H 6 GL (**23**), C.I. 56235 Disperse Yellow 105 [*14121-47-2*], is an intensely colored, lightfast, sublimate-free disperse dye. It is used to impart a yellow color to polyesters [23] and is prepared by reacting benzo[*k,l*]-thioxanthene-3,4-dicarboxylic anhydride with aminomethoxypropane. If the latter is replaced by stearylamine, a compound is formed that is particularly useful for dyeing plastics in bulk, mineral oils, fats, and waxes [24].

Compound **24** [*18014-08-9*] can be employed as a disperse dye, with good lightfastness, to impart a brilliant pink color to polyesters [25]. Compounds **23** and **24** are also classified as naphthalimide dyes.

Disperse dye **25**[*35763-62-3*] and its isomer **25a** give a very brilliant yellowish-red color having moderate lightfastness when applied to polyesters [26]. The naturally occurring dye Iachnanthofluorone (**26**) [*53766-48-6*] is a red fluorescent xanthene derivative that is closely related to compounds **23**–**25** [27].

6. Naphtholactam Dyes

Naphtholactam dyes have colors ranging from yellow to red and are suitable for dyeing polyesters and, in some cases, polyamides [28]. Although they show excellent lightfastness, these dyes do not have the high molar extinctions nor the quantum yields of, for example, the coumarins. Naphthostyril [*130-00-7*] (the lactam of 1-aminonaphthalene-8-carboxylic acid) reacts with a weakly basic aromatic or heterocyclic amine or with a reactive methylene group (e.g., a barbituric acid derivative) in the presence of phosphoryl chloride in an inert solvent to yield naphtholactam dyes. Compound **27** [*67880-03-9*] is obtained if the reaction is performed with 2-cyano-4-nitroaniline [29], as shown below; this compound produces a reddish-yellow color when used as a disperse dye with polyesters.

The disperse dye **28** [*58470-74-9*] gives a yellowish-red color with good lightfastness when applied to polyesters [30]; it is especially suitable for textile printing.

28

Compound **29** can be used to dye polyamides orange with a high degree of lightfastness [31].

29

Polyesters can be dyed orange to red with a high degree of lightfastness by using dyes typified by compound **30** [32].

R = H, alkyl, or alkoxy

30

7. Azlactone Dyes

Azlactones are formed by condensation of benzoylglycine (hippuric acid) with an aromatic aldehyde in the presence of acetic anhydride and sodium acetate.

Although azlactone dyes of the donor-acceptor type (**31**) are very brilliant, they are not lightfast. However, the greenish-yellow disperse dyes (**32**) [*25744-09-6*] and (**33**) [*51202-86-9*] can be effectively used on polyesters. They possess excellent coloring power and lightfastness [33], [34].

R = alkyl

31

32

33

8. Methine Dyes

Methine dyes (→ Methine Dyes and Pigments) are cationic dyes that are used to color polyacrylonitrile and acid-modified polyester fibers. Dye **34** is a fluorescent greenish-yellow [35] and is synthesized by condensation of 1,3,3-trimethylindoline-2-ylidene acetaldehyde [*84-33-3*] (Fischer base aldehyde) with 3-phenyl-2-pyrazoline [*936-47-0*].

34

Dye **35** is formed by coupling diazotized *p*-toluidine to 1,3,3-trimethyl-2-(3-chloro-1-propylidene)indoline [36]. This product imparts a fluorescent, lightfast, orange color to polyacrylonitrile.

35

Another methine dye (**36**) [*23406-34-0*] colors polyacrylonitrile a brilliant red, but with only moderate lightfastness [37].

Dye **36** is formed by the condensation of 1,3,3-trimethyl-2-methyleneindoline with 4-(*N*-methyl-*N*-cyanoethylamino)benzaldehyde.

9. Oxazine and Thiazine Dyes

Oxazine dyes (→ Azine Dyes), such as Basic Blue 3 (**37**), C.I. 51004 [*63589-47-9*], are used predominantly to color polyacrylonitrile a greenish-blue [38]. Some of these dyes, including **37**, are employed as laser dyes [39].

Thiazine dyes, e.g., dye **38**, exhibit fluorescence at long wavelengths from 650 to 680 nm and are also used as laser dyes.

Some dioxazines are also fluorescent dyes; dye **39** imparts a fluorescent, yellowish-red color to polyamides [40].

10. Miscellaneous Fluorescent Dyes

Diphenyl Brilliant Flavine 7 GFF (**40**), C.I. Direct Yellow 96 [*61725-08-4*] [41], can be regarded as an optical brightener (→ Optical Brighteners) which absorbs light in the visible region of the spectrum. Its maximum absorption is shifted to longer wavelengths in comparison with stilbene systems due to its more extensive conjugation. It is used as a direct dye for coloring cellulose fibers greenish-yellow (see bottom).

Disperse Yellow 77 (**41**), C.I. 70150 [*22281-18-1*] [42], can be prepared by acylation of 1-aminoanthraquinone with acetic anhydride, followed by condensation with anthranilic acid and zinc chloride at 100 – 110 °C. Both steps are carried out in the same reaction vessel.

Compound **41** is a brilliant, fluorescent, disperse dye that can be used to dye polyesters; it produces a greenish-yellow, sublimation–fast color with especially good lightfastness.

Fluorol 242 (**42**), C.I. 68410 [*6871-92-7*], a derivative of anthraquinone [43], is synthesized by replacing the bromine atom of 4-bromo-6-aminoanthrapyrimidine with an octadecylamino residue, followed by acylation with butyric chloride. Compound **42** is a fluorescent, yellowish-green dye and is suitable for dyeing fats and oils [24].

Solvent Green 5 (**43**), C.I. 59075 [*2744-50-5*], is a heat-resistant, lightfast dye [44]. It is used to color thermoplastic materials yellow in bulk and is suitable for material testing (see Chap. 11).

Perylenetetracarboxylic acid diarylimide derivatives typified by **44** [45] are used in the bulk dyeing of plastics (→ Naphthalimide Dyes). They produce extremely lightfast, red colors and are suitable for the production of fluorescent collectors (see Chap. 11).

The vat dye Thioindigo Red B (**45**), C.I. 73300 [*522-75-8*], is not fluorescent. However, this substance and its derivatives can be used conveniently in the bulk dyeing of plastics. They dissolve in the plastic material producing lightfast, heat-resistant fluorescent colors [48]. Asymmetrical thioindigo derivatives are suggested as especially suitable for the bulk dyeing of polyesters [47].

The naphthyridine dione dye Ciba Lake Red B (**46**), C.I. 73095 [*6417-51-2*] [48], has also been recommended for the bulk dyeing of plastics; it produces red fluorescent shades. This dye is synthesized by the acylation of indigo with phenylacetyl chloride and ring closure.

Azo coupling of 5-nitro-2-aminoindazole to 2,4,6-tris(*N*-dimethylamino)pyrimidine yields Azo Orange (**47**). Compound **47** is not itself fluorescent, but is converted to the yellow fluorescent dye **48** [*38432-19-8*] by treatment with acid [49]. Compound **48** can be used as a disperse dye to impart a lightfast, yellow color to polyesters. The formation of **48** from **47** illustrates that the stiffening of a molecular structure can convert a nonfluorescent azo dye into a fluorescent system.

11. Special Uses

The general uses of fluorescent dyes as colorants for fibers and plastics have been described in the preceding sections. This chapter describes special applications of fluorescent dyes, but does not include their use as laser dyes [50] because this is a separate keyword (→ Laser Dyes). Fluorescent daylight pigments are treated in Chapter 12.

Photochemistry. A variety of fluorescent dyes, in particular xanthene dyes (e.g., Rose Bengal), are used as sensitizers in photochemistry [51].

Material Testing. Fluorescent dyes, e.g., Solvent Green 5 (**43**), are used in the testing of materials to detect microflaws in the surfaces of metals (→ Nondestructive Testing).

Fluorescent Collectors. Fluorescent collectors consist of highly transparent plastic sheets, e.g., poly(methyl methacrylate), which are colored with a fluorescent dye. Exposure of the sheets to diffuse sunlight produces fluorescent light, which is then concentrated and collected by total internal reflection and released from the thin surfaces at the edges of the sheets. The collected light energy can be used to produce electricity by means of solar cells (→ Solar Technology) [52]. Dyes typified by **44** have proved to be most useful for this purpose.

Indicators. Fluorescent dyes are used as indicators in analytical titrations (→ Indicator Reagents).

In precipitation titrations, the fluorescent dye is adsorbed to the surface of the precipitate and undergoes a clearly recognizable change in fluorescence at the end point. Silver ions can be titrated in this way, using fluorescein (**15**) or Rhodamine 6 G (**17**) as an indicator.

Another class of fluorescent indicators consists of water-soluble compounds whose fluorescence changes at the end point. These indicators permit the titration of turbid or colored solutions. Thiols, for example, can be titrated with organic mercury compounds using fluorescein as an indicator.

Derivatizing Reagents. Substances that are normally very difficult to detect (amines, amino acids, peptides, sugars, carboxylic acids, and lipids) can be converted into their fluorescent derivatives with a suitable reagent. The derivative is then separated by means of TLC or HPLC and its fluorescence is measured. Detection sensitivity is very high; aniline, for example, can be detected at a concentration of 2 ng/mL [53]. Examples of such reagents are given in Table 2 (compounds **49**–**53**).

Compounds **52** and **53** are particularly interesting fluorogenic compounds because they produce intensely fluorescent derivatives, although they themselves do not fluoresce.

Fluorescent Probes. Fluorescent probes permit measurement of various parameters in cellular systems. For example, the pH can be measured by treating thin tissue sections with a fluorescent pH indicator, such as 4-methyl-7-hydroxycoumarin (**54**) [*90-33-5*] ($pK_s = 7.6$) [54].

54

Other fluorescent probes are used to determine the partial pressure of oxygen, the membrane potential, the redox status, the degree of lipophilia, viscosity, etc. [55]. Interference caused by the addition of foreign fluorescent probes can often be avoided by exploiting the intrinsic fluorescence of many natural products, such as thiamine [56]. Test strips coated with fluorescent probes have attained considerable importance in medical diagnostics [57]. For example, theophylline in serum may be determined by this method. Fluorescence-based immunoassays have also been developed (→ Diagnostic Reagents, Chap. 3.3.3.)

Enzyme Substrates. Enzyme activity can be measured by allowing enzymes to act on a substrate to produce an intensely fluorescent product. Suitable substrates are provided by the carboxylic acid esters, phosphates, and sulfates of highly fluorescent phenols with pK values between 6 and 9 such as 4-methyl-7-hydroxycoumarin (**54**), fluorescein (**15**), and 2-hydroxy-3-naphthoic acid (**55**) [*92-70-6*].

55

The glycosidic ethers of these phenols formed with a variety of sugars (e.g., glucose and galactose) are important in determining the activity of enzymes that cleave sugars.

Esters formed from compound **54** and long-chain fatty acids are commercially available and are suitable for measuring the activity of carboxyl esterases. The palmitic acid ester of compound **55** exhibits very weak fluorescence at 400 nm and is cleaved to palmitate and **55** by the

Table 2. Reagents used to synthesize fluorescent derivatives for chemical analyses

Name	CAS registry number	Structural formula	Derivatized compounds
Naphthyl isocyanate (**49**)	[*86-84-0*]		alcohols and amines
1-Dimethyl-5-naphthalene-sulfonyl chloride (dansyl chloride) (**50**)	[*605-65-2*]		amines and phenols
Fluorescein isothiocyanate (FITC) (**51**)	[*27022-45-3*]		amines, amino acids, and proteins
1,2-Benzenedicarboxaldehyde (*o*-phthalic anhydride, OPTA) (**52**)	[*643-79-8*]		primary amines
N-4-(2-benzimidazolyl) phenylmaleimide (BIPM) (**53**)	[*27030-97-3*]		thiols

enzyme lipase. Since compound **55** fluoresces very intensely at 460 nm, the rate at which the intensity of fluorescence increases can be used to measure enzyme activity (direct continuous kinetic assay) [58].

12. Daylight Fluorescent Pigments

Pigments are particulate solids which, unlike dyes, are practically insoluble in the medium to which they are added. Most daylight fluorescent pigments consist of finely divided resin particles that contain daylight fluorescent dyes. Their luminosity and brilliance make them particularly useful if intense or long-distance visibility is needed.

Daylight fluorescent pigments absorb UV and visible light from daylight and reemit it at a higher wavelength as visible radiation. As a rule, the time interval between light absorption and emission is very short (10^{-8} s), and the fluorescence persists only in the presence of an exciting light source. These pigments should not be confused with UV fluorescent pigments, which only fluoresce under UV light, or with phosphorescent pigments, which continue to emit light in the dark.

12.1. Production

Very few pure crystalline pigments have daylight fluorescent properties; one such substance, however, is Pigment Yellow 101, C.I. 48052 [*2387-03-3*] [59]. Most daylight fluorescent pigments are composed of one or more fluorescent dyes and a solid dye-carrying substrate or matrix. Optical brighteners, UV absorbers, or ordinary pigments (e.g., phthalocyanines or titanium dioxide) are sometimes also included. The matrix has a high affinity for the dye, thereby protecting it from environmental influences. Fluorescent pigments can be prepared by adsorbing fluorescent dyes onto the surface of fine silica gel particles [60], but selected grades of polymers are usually used as matrices.

12.1.1. Dyes for Daylight FluorescentPigments

Many dyes exhibit daylight fluorescence, but very few are useful for making pigments; the most important are listed in Table 3.

Table 3. Dyes for daylight fluorescent pigments

C.I. number	CAS registry number	Color
Solvent Yellow 44 (**2**)	[*2478-20-8*]	yellow
Solvent Yellow 160 : 1	[*61902-43-0*]	greenish-yellow
Basic Yellow 40	[*12221-86-2*]	greenish-yellow
Basic Red 1	[*989-38-8*]	pink
Basic Violet 10 (**16**)	[*81-88-9*]	pink
Acid Red 52 (**18**)	[*3520-42-1*]	pink

The concentrations of the dyes in the matrix range from ca. 0.1 to 10 wt %. Red fluorescent dyes exhibit the highest emission intensity at a concentration of ca. 0.5 wt %. Yellow dyes may be added at a concentration of up to 10 wt % without causing appreciable quenching. Mixtures of fluorescent dyes very often emit light at a higher intensity than that produced by the separate dyes; this is due to sensitized fluorescence. Sensitized fluorescence is one of the basic principles used in the production of fluorescent pigments and occurs when a portion of the excitation energy of one dye is transferred to a second dye with similar electron energy levels. The second dye is thus excited (sensitized) and fluoresces. Bright fluorescent yellow, orange, red, pink, and magenta shades are obtained by mixing yellow, pink, and violet dyes.

12.1.2. Pigment Matrices

Most fluorescent pigments are based on toluenesulfonamide–melamine–formaldehyde resins that are prepared by *bulk polymerization.* The fluorescent dyes are added to the partially polymerized monomers. Further reaction yields a highly condensed, colored resin, which solidifies when cooled and is then pulverized to give a fine pigment powder [61], [62]. The pigments may also be prepared by *emulsion polymerization,* in which the colored precondensate is further reacted after being mixed at high speed into, for instance, a liquid resin [63] or a molten wax [64]. This results in the formation of spherical pigment particles.

Other matrices are based on benzoguanamine–formaldehyde resins which are prepared by emulsion polymerization in an aqueous phase [65]. For further details of bulk and emulsion polymerization, see → Polymerization Processes.

Pigments based on polyamide [66] and polyester matrices [67] are highly resistant to temperature. Nonplasticized poly(vinyl chloride) and its copolymers [68], urethane resins derived from isocyanates, and compounds containing hydroxyl groups [69] have also been used as pigment matrices.

12.2. Quality Specifications

Daylight fluorescent pigments are offered in a series of colors with carriers having the same basic structure. Properties, such as color strength, solubility, particle size, and resistance to solvents, light, and heat, differ within the various series. Special series are available for most applications to satisfy the specific requirements of processing techniques and formulations.

Fluorescent pigments are generally fine powders with a particle size of 2 – 10 µm. They are easily dispersed in commonly used binders, resin vehicles, and polymers.

Since the pigments are translucent, optimum fluorescence is obtained by applying them to a dense white surface. They are slowly degraded when exposed to sunlight but incorporation of UV absorbers ensures optimal colorfastness. Thick, highly pigmented films are generally recommended for exterior applications. The pigments are almost indefinitely stable to indoor illumination.

At specific wavelengths, daylight fluorescent pigments reflect more light than a white surface does. This is because normal reflectance is reinforced by the emission of fluorescent light. A white surface reflects a maximum of 100 % of the incident light, whereas daylight fluorescent pigments can show total reflectances of over 240 %. Examples of pigment reflectances at different wavelengths are listed in Table 4.

Figure 1 shows typical reflectance curves for an orange, daylight fluorescent surface and a conventional nonfluorescent surface. The high luminance of the fluorescent surface results from

a 3 – 4-fold higher reflectance value at the peak emission wavelength. Fluorescent pigments are a powerful source of monochromatic light.

Table 4. Spectrophotometric parameters of daylight fluorescent pigments

Color∗	Peak wavelength of emission, nm	Reflectance, %
Blue	450	65
Green	520	75
Yellow	530	170
Orange	610	240
Red	620	210
Pink	625	215

∗ Tests were conducted on pigments from the Radglo R series (Radiant Color, Belgium)

Figure 1. Reflectance spectra of colored surfaces
a) White; b) Conventional orange (Pigment Red 104, C.I. 77605 [*12656-85-8*]); c) Daylight fluorescent orange (Radglo Fluorescent Orange R 13, Radiant Color, Belgium)

12.3. Uses

Many military, civil, and industrial authorities stipulate the use of fluorescent colors where safety, high visibility, and rapid identification are important. Typical applications are the marking of danger areas, aircraft, ambulances, naval vessels and buoys, safety clothing, traffic signs, and symbols on slow-moving vehicles.

As a result of their striking visual impact, daylight fluorescent pigments are used to enhance a wide range of products (e.g., consumer goods, packagings, coated papers, and textiles), as well as for publicity and advertising. As UV-responsive colors, these pigments are employed in the coding and tracing of documents, in theater scenery, and in entertainment decorations. The wide demand for daylight fluorescent pigments has resulted in the development of special products for printing, coating, and painting applications. The use of fluorescent pigments in the plastics industry has almost unlimited possibilities.

12.4. Toxicology

Daylight fluorescent pigments are considered to be nontoxic and are not radioactive. They do not contain inorganic phosphorus, and heavy metals are only found in trace amounts. However, the pigments do not have FDA approval and therefore, should not be used in connection with food.

1. Introduction

Under normal conditions, fluorine [*7782-41-4*] is a pale yellow gas of stinging odor, which rapidly causes suffocation. Having the atomic number $Z = 9$, it occupies an extreme position in the Periodic Table: at the top of Group 17, the last element before neon, the closest rare gas. Its electronic configuration ($1s^2\ 2s^2\ 2p^5$) makes it the first halogen.

This permits prediction of the strong electronegativity of the fluorine atom, which seeks to take on the electron configuration of neon by capturing an electron. This tendency and the virtual impossibility for an electron of the atom to occupy a higher energy level make fluorine an essentially univalent element [9].

This structure also leads to the formation of the diatomic F_2 molecule, the most highly oxidizing stable substance known. This extreme oxidizing power explains the nonexistence of the F_2 molecule in nature and the impossibility of obtaining it by the action of an oxidant on the fluoride ion, F^-. The only method of preparing elemental fluorine is electrolysis in nonaqueous media.

Fluorine was prepared for the first time in 1886 by the French chemist Henri Moissan, by electrolysis of a solution of potassium fluoride in anhydrous hydrogen fluoride [*7664-39-3*] [10]. The name fluorine comes from the Latin *fluere*, meaning *to flow*, by reference to the main fluorine ore, fluorite, CaF_2, used as a metallurgical flux. Until World War II, fluorine remained a laboratory curiosity.

The discovery of nuclear fission, with all its military and civilian implications, brought about rapid development of the production of fluorine, a necessary intermediate in isotope concentration via uranium hexafluoride.

2. Properties

2.1. Physical Properties

Fluorine has a relative atomic mass A_r of 18.998403 [11]. Its electron affinity is 333 kJ/mol. The fluoride ion is the smallest anion, with an ionic radius of 136 pm; this small size promotes the formation of hydrogen bonds in compounds involving the F^- ion. Depending on the scale used, the electronegativity of fluorine is 4.10 (Allred–Rochow), 3.98 (Pauling), or 3.91 (Mulliken).

The fluorine molecule, F_2, M_r 37.997, is small. The values of the F–F distance determined by electron diffraction [12] and Raman spectroscopy [13] are in agreement, and the currently accepted value is 141 pm. The covalent

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a11_293

radius of the F atom is therefore 71 pm, making fluorine the smallest halogen. The value of the F–F bond energy has been the subject of numerous controversies; the most recent value is 158.3 kJ/mol [14]. This energy is low and contributes to the high reactivity of the fluorine molecule, frequently leading to highly exoenergetic reactions.

The most important physical properties of the F_2 molecule are given in Table 1; the essential thermodynamic properties are listed below:

Enthalpy of fusion ΔH_f^0	509 J/mol
Enthalpy of vaporization ΔH_v (85.0 K)	6509 J/mol
Standard entropy S^0	203 J mol^{-1} K^{-1}
Standard heat capacity C_p^0	31.3 J mol^{-1} K^{-1}

The reversible potential of the standard fluorine electrode, 2.85±0.04 V, has been calculated from the free enthalpy of formation of HF in aqueous solution [15] but is impossible to achieve experimentally. It is high as a result of the very high solvation energy of the F^- ion in water.

Table 1. Physical properties of fluorine

Melting point *mp*	53.5 K
Boiling point *bp*	85.0 K
Critical temperature τ_{crit}	144 K
Critical pressure p_{crit}	5.571 MPa
Density of the solid ϱ_s	1900 kg/m^3
Density of the liquid ϱ_l	
at 66.0 K	1633 kg/m^3
71.0 K	1608 kg/m^3
77.2 K	1562 kg/m^3
85.0 K	1512 kg/m^3
Density of the gas ϱ_g (STP)	1696 kg/m^3
Viscosity of the liquid η_l	
at 69.2 K	0.414 mPa s
85.2 K	0.257 mPa s
Viscosity of the gas η_g (STP)	0.0218 mPa s
Thermal conductivity λ of the gas (STP)	0.0248 W m^{-1} K^{-1}
Dielectric constant ε of the liquid at 71.2 K	1.54

Vapor pressure of fluorine:

T, K	50.2	59.0	65.5	70.5	80.0	85.0
p, kPa	0.1	1.3	5.3	13.3	53.3	101.3

From an industrial point of view, it is more useful to know the minimum decomposition voltage of HF, taking into account the reaction for the electrolytic production of fluorine:

$$2\,HF \rightleftharpoons H_2 + F_2$$

This voltage, calculated under the conditions achieved in industrial electrolyzers (KF · 2 HF medium, 85° C) is $U_{decomp.} = 2.901$ V [16].

This is actually the most probable value, after a series of determinations frequently lacking in homogeneity, as noted by A. T. Kuhn is his review article [17].

2.2. Chemical Properties

The chemical properties of fluorine are determined by its very powerful oxidizing nature, which frequently leads to sudden or even explosive reactions. The simplest fuel, hydrogen, combines with fluorine in a highly exoenergetic reaction without the need for external initiation.

Reaction with water forms, in addition to HF, hydrogen peroxide [*7722-84-1*], H_2O_2, and oxygen fluoride [*7783-41-7*], OF_2, which cannot be obtained by direct reaction. Compounds in aqueous solutions are generally oxidized by a complex process, with oxoanions forming peroxoanions and metal ions being brought to their highest oxidation state. For example, the chlorate ion, ClO_3^-, is oxidized to perchlorate ion, ClO_4^-. The phosphate ion, PO_4^{3-}, is converted to ortho and pyro perphosphate ions.

Fluorine combines with nonmetals to form compounds with unusual properties.

Thus, sulfur burns in fluorine to form sulfur hexafluoride [*2551–62–4*], SF_6, an extremely stable gas. This is the only hexahalogenated sulfur derivative, which is due to the low steric hindrance of the fluorine atom, permitting it to form the largest number of single covalent bonds with a given element.

Carbon and fluorine combine directly to form carbon tetrafluoride [*75-73-0*], CF_4, a particularly inert gas. The equivalent silicon derivative, SiF_4, in contrast, is very easily hydrolyzed. Controlled fluorination of carbon is possible, leading to the solids C_2F and CF.

Fluorine does not react directly with nitrogen, regardless of the temperature and pressure. However, nitrogen trifluoride [*7783-54-2*], NF_3, can be formed in an $N_2 + F_2$ plasma. This compound illustrates the particular nature of the reactions of fluorine: the low bond energy of the

F_2 molecule permits the reaction $N_2 + F_2$ to be thermodynamically favored, in contrast to the reaction $N_2 + Cl_2$:

$$N_2 + 3F_2 \longrightarrow 2NF_3 \quad \Delta H_f = -108.78\ \text{kJ/mol}$$
$$N_2 + 3Cl_2 \longrightarrow 2NCl_3 \quad \Delta H_f = +230.12\ \text{kJ/mol}$$

Two derivatives of phosphorus, PF_3 [*7783-55-3*] and PF_5 [*7647-19-0*], and their homologues, AsF_3 [*7784-35-2*], AsF_5 [*7784-36-3*], SbF_3 [*7783-56-4*], and SbF_5 [*7783-70-2*], are also known. Generally, the highest oxidation state is obtained.

Halogens react readily with fluorine, and numerous derivatives are known, such as ClF_3 [*7790-91-2*], ClF_5 [*13637-63-3*], BrF_3 [*7787-71-5*], BrF_5 [*7789-30-2*], IF_5 [*7783-66-6*], IF_7 [*16921-96-3*]. Chlorine trifluoride is a much more reactive fluorinating agent than fluorine itself, while IF_5 is a milder fluorinating agent.

Fluorine combines directly with the heaviest rare gases, i.e., those with the lowest ionization energy. The best known rare-gas fluorides are XeF_2, XeF_4, XeF_6, KrF_2, KrF_4. The above compounds are obtained by the prolonged action of fluorine at high temperature and most frequently under pressure; these compounds show structural analogies with the halogen fluorides.

Fluorine reacts with numerous oxygenated derivatives of metalloids and can lead to addition products. Chlorine dioxide, ClO_2, forms ClO_2F; nitric oxide, NO, leads to nitrosyl fluoride, NOF; and NO_2 forms nitryl fluoride, NO_2F. Fluorophosgene, COF_2, yields trifluoromethyl hypofluorite, CF_3OF. All of these compounds are gases. The action of fluorine on a chlorate produces ClO_3F, while concentrated perchloric or nitric acid produces ClO_4F and NO_3F, perchloryl and nitryl oxyfluoride, respectively.

Numerous metals react suddenly with fluorine, and these reactions have presented numerous problems for the industrial production of fluorine. The critical point in the F_2–metal reactions is the formation of a compact surface film of fluoride, opposing the diffusion of fluorine and of the metal itself. This is referred to as passivation. Under these conditions, passive iron and steel are highly resistant to fluorine, provided the temperature is below 200 °C. Above 200 °C only nickel and a nickel–copper alloy (70 wt % Ni–30 wt % Cu) show sufficiently stable passivation.

Certain non-oxidizable metals, such as the noble metals, show good resistance to fluorine at low temperature, but are rapidly destroyed above a certain temperature by the formation of a volatile fluoride, such as PtF_4.

Fluorine also reacts with metal compounds and, in particular, with halogenated compounds, from which it displaces the halogen. With a few exceptions, this reaction leads to the maximum oxidation state of the metal. The direct fluorination of chromium stops at CrF_5. Chromyl fluoride, CrO_2F_2, is obtained by fluorination of the chloride.

With manganese, the reaction does not go beyond MnF_3, even upon fluorination of the permanganate ion. On the other hand, in the presence of KF, an oxidation state of +4 is stabilized in the form of $KMnF_5$. Likewise, nickel leads directly only to the difluoride, NiF_2, but in the presence of KF, K_2NiF_6 can be prepared. Cobalt forms the trifluoride CoF_3 [*10026-18-3*], while tantalum and niobium form the pentafluoride.

Uranium leads to the hexafluoride UF_6, a gaseous compound essential in the nuclear fuel cycle, but many other metals also form a volatile hexafluoride, including rhenium, iridium, molybdenum, tungsten, osmium, neptunium, plutonium, and technetium.

The direct action of fluorine on hydrocarbons is most frequently destructive. The energy released in the reaction is such that it causes rupture of the C–C bonds, and it is therefore appropriate to dilute the fluorine to a very low concentration in an inert gas or to work in a solvent. In the liquid phase, the organic molecule is diluted in a fluorine-resistant solvent, most frequently at low temperature, and by introducing the fluorine diluted with nitrogen or argon.

Direct fluorination generally leads to a mixture of perfluorinated compounds, and it is extremely difficult to obtain a partially fluorinated product. Furthermore, partial destruction of the molecule cannot be prevented, with saturation of the double bonds. Provided that the rings of aromatic compounds are preserved, the homologous cyclic perfluorinated derivatives are obtained. Under certain conditions, fluorination preserves the hetero atoms present in the organic chain, especially O and N. For example, perfluorinated ketones and amines can be obtained from their hydrocarbon homologues.

3. Mineral Resources

While the element fluorine does not exist in nature in the form of F_2, because of the extreme reactivity of this molecule, the element is very widespread in nature in the combined form. The earth's crust contains between 0.06 and 0.07 wt % of fluorine, putting this element in thirteenth place on the scale of abundance. Numerous inorganic compounds contain fluorine, but, on the industrial level, only three families of products represent economically exploitable starting materials:

1) *Natural cryolite*, $AlF_3 \cdot 3NaF$ [*15096-52-3*]. This is the richest ore, very widely exploited since the early days of commercial aluminum production, but now practically exhausted and abandoned in favor of synthetic cryolite.
2) *Fluorite* or fluorspar, CaF_2 [*7789-75-5*]. Presently the most widely exploited ore [18].
3) *Fluorapatite*, $Ca_5(PO_4)_3F$ [*1306-05-4*]. Fluorine is a byproduct of the fertilizer industry. This is certainly the ore of the future because it represents the world's largest reserve of fluorine.

In 1984, the world capacity for CaF_2 production (from fluorite and fluorapatite) was estimated at 6.5×10^6 tonnes. There are three commercial grades of CaF_2: acid, ceramic, and metallurgical. It is the acid grade ($\geq$97 % CaF_2) that is used in the manufacture of hydrogen fluoride, the starting material for the electrochemical production of fluorine.

The presence of fluorine compounds in many ores and their leaching result in natural soft waters frequently containing 0.2 mg/L of fluoride ions. Sea water has a distinctly higher content, from 1 to 1.4 mg/L.

Finally, fluorine compounds exist in traces in numerous living organisms. In the human body, fluorine is an important trace element in the teeth and bones at the level of $1-2 \times 10^{-3}$ wt % (dry product).

4. Industrial Production

Except the laboratory-scale method described in [19], it is presently not known how to prepare fluorine commercially by a purely chemical method, i.e., starting from a fluorine derivative that has itself been obtained without the participation of elemental fluorine.

All fluorides are in equilibrium with fluorine:

$$MF_{x+y} \rightleftharpoons MF_x + y/2\ F_2$$

Complex fluorides are known which show a high fluorine vapor pressure below 900 K.

The fluorine complexes of Ni(IV) are capable of oxidizing the fluoride ion to fluorine [20]:

$$K_2NiF_6 + KF \xrightarrow{673\,K} K_3NiF_6 + \frac{1}{2}\ F_2$$

This reaction has been proposed for the preparation of extremely pure oxygen-free fluorine, but these fluorides are themselves prepared by the action of fluorine, and it is not known how to prepare them otherwise.

In view of this, the only method for the production of fluorine, both in the laboratory and in industry, is the electrolysis of anhydrous hydrogen fluoride containing dissolved potassium fluoride to achieve sufficient conductivity. It is important to work in as anhydrous a medium as possible, to prevent the formation of oxygen, or oxygen fluoride, at the anode. In all cases, hydrogen is produced at the cathode and fluorine at the anode.

4.1. History

Following the historic preparation by H. Moissan in 1886, which was carried out in a platinum U tube, with platinum electrodes, ca. 30 years went by without any significant improvement. For example, the German chemist O. Ruff, a pioneer in the chemistry of fluorine compounds, used an apparatus very similar to that of H. Moissan for his work. This process used an electrolyte rich in HF ($\geq$60 wt %) but below ambient temperature to limit the vapor pressure of HF.

At the end of World War I, W. L. Argo and his co-workers [21] were the first to use a fused electrolyte and a graphite anode. This involved a so-called high-temperature cell, with a $KF \cdot HF$ medium, which has a melting point of 512 K.

This new technology represented an important advance, because it avoided the use of platinum, which is strongly corroded in the Moissan

process. However, two major problems arose: the excessively rapid increase in the melting point with the consumption of HF, and a phenomenon of anode passivation, referred to as the *anode effect.*

Mastery of the KF · HF phase diagram goes back to G. H. Cady [22]; this diagram makes it possible to understand the difficulties in using the high-temperature cells: the bath used is located in a range in which the melting point is sensitive to the HF concentration (see Fig. 1).

Figure 1. Phase diagram of the system KF · xHF
The dotted lines are isobars of HF vapor pressure above the liquid: a) 50 mm Hg (6.7 kPa); b) 100 mm Hg (13.3. kPa); c) 250 mm Hg (33.3 kPa).

The anode effect is a phenomenon often observed in fused-salt electrolysis. It consists of a sudden or progressive increase in voltage at the terminals of the cell for a constant imposed amperage. A considerable amount of work has been devoted to this phenomenon, which was originally attributed to the presence of an insulating gas film on the anode surface. However, it was observed that the wettability of the anode by the electrolyte decreased considerably after voltage was applied, thus promoting spreading of the gas film. It was O. Ruff who suggested in 1936 that a surface compound of the type CF_x, not wetted by the bath, could be formed.

Since that date, the presence of this compound has been demonstrated and is now an acknowledged fact [23], [24]. Apparently, electron transfer through this barrier layer of fluorinated carbon takes place by a tunnel effect. This mechanism has a high activation energy, which is the origin of the high overvoltage of the fluorine anode [25]. In normal operation, this passivating film protects the carbon against destruction. Under certain more or less well-known conditions, electron transfer is completely blocked.

Industrially, various means are attempted to prevent or retard the anode effect (see4.3).

For 25 years (1919 – 1944), 80 % of the cells described in the literature were of the high-temperature type. However, P. Lebeau and A. Damiens, starting in 1925, may be considered as forerunners in the use of a medium-temperature technology [26]. They used the salt KF · 3HF, which has a melting point of 65.8 °C (see Fig. 1). The anode was made of nickel, and it suffered severe corrosion. In 1942, G. H. Cady described a cell using the salt KF · 2HF, with a melting point of 71.7 °C [27], and an anode made of either nickel or carbon. This date marks the start of the industrial development of fluorine production linked to the exploitation of nuclear fission. This development became more intense at the end of World War II. The fluorine industry is a new industry, only about forty years old, which has grown together with the nuclear industry.

For numerous applications, such as the fluorination of organic compounds, only small quantities of fluorine are required. Since fluorine storage requires an appropriate technology, it may be advantageous to have electrolysis cells available on a laboratory scale. Cells of this type have been supplied by ICI to universities and industry for many years [32].

In all modern fluorine-production units, the electrolyte has the approximate composition KF · 2HF (40.8 wt % HF) and a temperature ranging from 80 to 110 °C [28–31]. The main characteristics of several industrial cells are listed in Table 2. As an example, the usual COMURHEX – ATOCHEM fluorine cell is shown schematically in Figure 2. The new French double-size cell (12 kA) is shown in Figure 3. Other cell designs have been reviewed in the literature [1], [28], [31].

Table 2. Main characteristics of four industrial fluorine cells

Construction feature or operating characteristic	Union Carbide (USA) [29], [32]	ICI (UK) [29]	COMURHEX (France) [33], [34]	Montecatini (Italy) [35]
Electrolyte composition				
% HF	40 – 42	40 – 41.5	40	39 – 41
Electrolyte capacity, t	1.55	1.73	2.4	1.25

Figure 3. The new French 12-kA fluorine cell

New cell designs are described in the patent literature [36], [37] but are not fundamentally different from the classical cells.

4.2. Cell Tanks, Cooling Systems, Skirts, and Diaphragms

Monel (nickel – copper alloy) is frequently used for the cell-tank construction; mild steel tanks, sometimes operating at cathode potential to minimize corrosion, are also used [38]. The corrosion rate of metals in contact with the vapor phase is lower than that of the tank walls in contact with the electrolyte. In fact, the use of Monel

as a cell-cover material is not required: mild steel or Monel-clothed steel are adequate.

During electrolysis, a large quantity of heat resulting from the Joule effect must be removed so that the cell can operate at a constant temperature; for this purpose, the French cell is surrounded by a water jacket and additional Monel cooling tubes are suspended through the cover. When the cell is shut down, the electrolyte must be kept molten, and heat is then supplied by introducing steam through the Monel tubes. In other types of cells, circulation of the electrolyte is used to promote the removal of heat during electrolysis [39].

Monel, magnesium, or steel skirts are used to separate the hydrogen and fluorine produced by electrolysis. In some cells, a diaphragm (i.e., a skirt extending further into the electrolyte and with an immersed part, which may be perforated) helps to direct the flow of the gases as they are released. The use of a diaphragm results in a better current efficiency, but the ohmic drop is higher, and thus the operating voltage is also higher. The greatest benefit of the diaphragm is to prevent broken anodes from touching cathodes thus avoiding damage to the cell caused by short circuits. Considerable bipolar corrosion of metallic skirts is observed, because the surface of the metal exposed to the cathode becomes anodic. This problem may be overcome by positioning the cathode below the level of the skirt [40]. Small gaps between the skirt and highly permeable anodes are possible because the bubbles of fluorine escape through the interconnecting pores; larger gaps must be provided for low-permeability carbons, for the fluorine bubbles are evolved at the electrode surface.

4.3. Electrodes, Polarization, and Anode Effect

Metallic cathodes are used in all industrial cells. Copper and steel are suitable materials, but steel is preferred because of its lower cost. The corrosion rate of a metal dipped in the $KF \cdot 2HF$ electrolyte is not high if this metal acts as a cathode. The metallic cell body is no longer used as the cathode in industrial cells. In the French cells, the cathode is in the form of a box surrounding the anode assembly, with the cathode connections at the top of the cell. In the British cells, internally cooled cathodes have been used, with cathode connections being made under the cell.

The main cause of failure in medium-temperature cells is related to the anodes: polarization, the anode effect, and deterioration of the mechanical and electrical contact between the electrode and the bus bar. Graphite is not a satisfactory anode material, because of swelling and disintegration, but amorphous carbon is. Nickel anodes have been tested, but their corrosion reduces the current efficiency and insoluble nickel fluoride accumulates.

The difficulties encountered with carbon anodes in fluoride melts have been related to a wetting problem since the early years of fluorine electrochemistry [21]. The *anode effect* in fluoride melts has been reviewed by Rudge [29] and by Watanabe et al. [41]. To avoid this phenomenon, two solutions have been proposed: the first consists in using porous carbon anodes, with the bubbles escaping through the interconnecting pores. However, these electrodes are somewhat fragile and good electrical and mechanical contact between the carbon block and the bus bar is difficult to obtain. The second solution is to use low-permeability carbon anodes and to add nickel or lithium salts to the electrolyte in order to improve the wettability [42]. In the Union Carbide cells, fitted with low-permeability carbon anodes, no additives are deliberately introduced. Rudge [29] claimed that the low concentrations of nickel necessary to reduce the anode – electrolyte contact angle, originate from the corrosion of Monel skirts. In the same way, in the Allied Chemical (now Allied-Signal) cells, corrosion of magnesium alloy skirts occurs, and this introduction of magnesium fluoride has the same effect in promoting wetting of the anodes as the deliberate addition of LiF [29].

A Japanese patent describes the production of special types of carbon suitable for fluorine production [43]. To reduce polarization problems, the Harshaw anodes were impregnated with copper [44], whereas the anodes in the Du Pont cells were strengthened by impregnation with carbonaceous materials and rebaking [31].

High-permeability carbons to overcome polarization problems have been suggested by Howell et al. [45]. The same authors have built a fluorine cell in which the hollow anode is wholly immersed in the electrolyte; F_2 is led away by a copper pipe, which also provides electrical con-

nections to the carbon [46]. More recently, composite carbon electrodes having an outer part with a higher porosity than the inner part have been patented [47], [48]. Finally, impregnation of anodes with lead salts has been proposed to suppress CF_4 formation during electrolysis [49].

Deterioration of the anode contact frequently occurs because it is subject to attack by fluorine, electrolyte, and hydrogen fluoride vapor. A metal rod screwed into the top of the carbon block can be used only if the carbon is very hard; anodes may also be bolted to a copper or steel hanger bar.

Improved electrical connections have been described in the patent literature. They are formed by electrodepositing [50] or spraying [51] a layer of copper or nickel and welding the electrical conductor to the electroplated or sprayed region of the electrode. Bottom-entering anodes sealed with frozen electrolyte have been successful only in laboratory cells. Polytetrafluoroethylene, loaded with 25–50 wt % powdered calcium fluoride, has been widely used as an insulator in packing glands supporting the anode and cathode conductor posts.

4.4. Electrolyte

The specific electrical conductivity κ of the electrolyte has been measured by Schumb et al. [52] over a wide range of temperatures and HF concentrations. The authors found: $0.12<\kappa<0.21\Omega^{-1}\mathrm{cm}^{-1}$.

A high HF content in the electrolyte actually promotes corrosion, misting, and anode polarization [53], whereas low HF contents lead to a decrease in the conductance and thus to an increase in the cell operating voltage [53].

During electrolysis, the composition of the melt changes, since HF is consumed. In many cells, the electrolyte level is maintained by the intermittent addition of gaseous HF, but control of the electrolyte composition is important, and HF should be added automatically to maintain a preselected optimum concentration. Circulation of the electrolyte is not necessary to maintain a uniform composition, because the rate of dispersion of HF is high, but good circulation is necessary to promote the rapid dissipation of heat from the cell.

The electrolyte $KF \cdot 2HF$ is prepared from commercial Frémy salt $KF \cdot HF$ [*7789-29-9*] and HF. Special care is taken in its preparation, because the purity of the fluorine produced and the anode behavior depend strongly on the electrolyte composition.

The COMURHEX specification (in wt %) for $KF \cdot HF$ is $KF \cdot HF$ 99.0 % min., K_2SiF_6 0.1 % max., H_2O 0.3 % max., SO_4^{2-} 0.01 % max., Na^+ 0.3 % max., Cl^- 0.001 % max., Fe, and Pb 0.001 % max. The specification for the HF used in electrolyte preparation and feeding of COMURHEX cells is HF 99.9 % min., H_2SO_4 0.05 % max., H_2SiF_6 0.05 % max., SO_2 0.005 % max., and H_2O 0.05 % max. The preparation of $KF \cdot 2HF$ is an exothermic reaction. Gaseous or liquid HF is added to the Frémy salt in a reaction vessel jacketed to control its temperature.

If it is not sufficiently pure, the electrolyte is treated with fluorine or preelectrolyzed, using a cell with a nickel anode. In particular, the water content must be reduced to avoid OF_2 and CO_2 evolution in the anodic compartment. The sulfate content must be low to avoid attack of the carbon anode [32] and SO_2F_2 [*2699-79-8*] evolution. Chloride and SiF_6^{2-} give rise to the evolution of chlorine fluorides (or oxychlorofluorides) and silicon tetrafluoride [*7783-61-1*], SiF_4. Other impurities, such as heavy metals, contribute to a rise in the cell operating voltage.

Some compounds deliberately or accidentally introduced into the melt have been reported to have a beneficial effect on the electrolytic process. For example, cell behavior is strongly influenced by the presence of nickel salts in the electrolyte, resulting from corrosion of nickel or Monel skirts, diaphragms, or cooling tubes [29]. The addition of lithium fluoride to the electrolyte is useful because it lowers the freezing point of the melt and reduces anodic polarization problems [40], [54]; however, the LiF concentration decreases with time, because it is progressively carried down into the sludge at the bottom of the cell, and the beneficial effects finally disappear [52]. Quantities from 1 to 2 wt % are used as standard additions to the melts. The critical current densities are increased by the addition of LiF; LiF is considered to promote the decomposition of the passivating film of $(CF)_n$ formed on the anode surface [55]; the addition of LiF, NiF_2, or AlF_3 has been reported to be effective in preventing the anode effect [56] by reducing

the anode – electrolyte contact angle [29]. During operation, the carbon anode is coated with a layer containing nickel or lithium ions; this layer is wetted by the electrolyte, and fluorine bubbles break away easily [42].

Finally, numerous other additives to the electrolyte have been proposed in a Japanese patent [57], and as a method for purification of the electrolyte [58].

The electrolysis of a mixture of NH_3 and HF (liquid at room temperature) has been studied [59–61]. Patents describe cells for the industrial production of fluorine using the NH_4F – HF system [62] or a mixture of NH_3, HF, and KF [63–65], but, this process is not yet in use because of corrosion of metals and carbon in this electrolyte.

4.5. Overall Industrial Process

The flow diagram of the French fluorine production plant is shown in Figure 4.

After preparation, the KF · 2HF electrolyte is transferred to the preelectrolysis cell for removal of water. After this important step, lithium fluoride is added to the electrolyte, and the electrolyte is transferred into the fluorine production cell.

Special techniques for the elimination of polarization have been developed: a new 6000 A cell is first started up at low current ($I = 1000$ A) for several hours. The current is increased step by step until steady-state conditions at 6000 A are established. During the low-voltage electrolysis, the last traces of water are removed; the anodic gases produced (i.e., fluorine contaminated with OF_2, CO_2, O_2) are diluted with nitrogen and destroyed.

The usual operating voltage is 8.5 – 10.5 V for $I = 6000$ A (corresponding to $j = 12$ A dm^{-2}). The current efficiency is about 90 – 95 % but the energy consumption is about 14 – 17 kWh/kg F_2, i.e., about four times the theoretical value. This large energy loss is mainly due to the high anodic overvoltage.

As a result of the electrolysis of HF, hydrogen is produced in the cathode compartment, while fluorine evolution takes place in the anode compartment. The cell off-gases contain hydrogen fluorine, whose concentration depends on the composition of the electrolyte and the cell operating temperature (average 6 % [66] or 10 % [67]. In the COMURHEX cell, this concentration is 7 – 10 %. The HF is separated from hydrogen or fluorine and reprocessed.

Other impurities in the cell off-gases, such as CO_2, O_2, or OF_2, may result from the electrolysis of traces of water in an insufficiently preelectrolyzed electrolyte. In the same way, sulfuryl fluoride (SO_2F_2) and silicon tetrafluoride result from the electrolysis of sulfate and fluorosilicate impurities. As shown by Downing et al. [67], the quantity of these compounds in the anodic gases, which may rise to several percent at the start-up of the cell, decreases rapidly, provided that purified HF is used to feed the cells. In addition, very low concentrations ($\leq$30 ppm) of tetrafluoromethane CF_4 and higher fluorocarbons are always observed during electrolysis. Their presence has been attributed to the continuous thermal decomposition of the graphite fluoride passivating layer [24]:

$$n\,CF_x \longrightarrow a\,C + b\,CF_4 + c\,C_2F_6 + d\,C_yF_z + \ldots$$

The CF_4 concentration is controlled by infrared spectrophotometry. When it is greater than 50 ppm, the operating voltage is reduced, in order to avoid anode deterioration. The percentage of O_2 and N_2 in anodic gases is determined by gas chromatography.

The operation of fluorine cells is not dangerous if special precautions are rigorously followed, e.g.:

1) Avoid contact with electrolyte, HF, or F_2.
2) Protective equipment must be worn by operators working near the cells: safety goggles, face shields, protective clothing, gloves. In addition, a gas mask with canister for acid-gas protection may be worn.
3) Prevent development of explosive gas mixtures within the cell (i.e., air leaks into the cathode compartment must be eliminated).
4) Reactive contaminants, such as grease, must be kept out of the system. If they are not, highly exothermic combustions take place, and the metal in piping or valves may melt and burst under pressure.
5) Fluorine plants must have forced ventilation systems to provide fresh air for personal comfort and safety.

5. Handling, Storage, and Transport

Handling [28], [68], [69]. Because of the reactivity of elemental fluorine, special care must be taken in handling this gas. A passivation of the whole system (line and apparatus) with F_2 is imperative before each operation. Corrosion of passivated piping and valves is not a serious problem if moisture and reactive contaminants, such as grease, are kept out of the system. The whole system must be carefully tested for leaks; manipulations require a dry, ventilated room. The selection of materials to be in contact with fluorine depends on the expected temperature. Aluminum, copper, stainless steel, nickel, brass, Inconel, and Monel have been proposed for industrial use. Tables of corrosion data have been presented and reviewed in the literature [69]. For the handling of pure fluorine under pressure, the use of nickel or Monel pipes is preferable.

Fluorine is not difficult to handle near atmospheric pressures: in 1947, Cady claimed that the hazards of working with fluorine had previously been greatly over-rated. However, handling fluorine under high pressure is a different matter [29].

At moderate temperatures, reactions can be carried out, usually on a laboratory scale, in quartz, Pyrex, Teflon (polytetrafluoroethylene), or Kel'f (polymonochlorotrifluoroethylene). Metallic equipment is necessary for work at relatively high temperatures. Laboratory equipment is reviewed in [70].

Storage [71–73]. Storage only relates to a small percentage of the production. Electrolyzers are integrated in SF_6 or UF_6 units, and the major part of the elemental fluorine produced is directly used in the plant. In order to avoid the handling of bottled fluorine, ICI supplied 10-A and 60-A laboratory-scale cells to universities and to industry for many years [29]. At present, the use of reliable cylinders of compressed fluorine is preferred.

Compression and Liquefaction. Fluorine requires purification before liquefaction. HF must be removed to prevent icing; this is accomplished by a combination of refrigeration and NaF absorption traps [72]. Heating fluorine to 300 – 400 °C before liquefaction is useful for destroying traces of impurities such as oxygen fluorides; if they are not removed, these compounds spontaneously explode when the liquid phase is warmed for evaporation.

The compression of pure fluorine with ordinary compressors is difficult because lubricants react with the gas. Compressors of the diaphragm type have been used successfully for low-pressure storage, but for higher pressures the method used involves liquefaction of F_2 by cooling with liquid nitrogen and later reevaporation of the gas to the desired pressure in the shipping container.

Transport. The French specification for the transport of fluorine is available from the "Imprimerie Nationale, Paris":

Transport by rail and road (April 25, 1945, and June 27, 1951)

Transport by air (January 14, 1983).

The European specification for transport by road (A.D.R.) is available from the United Nations (Geneva), and the specification for transport by rail (R.I.D.) can be obtained from the S.N.C.F. (Paris).

Fluorine must be packaged under a pressure not exceeding 2.86 MPa (28 bars); the steel cylinders, previously tested at 200 bars, must be equipped with special valves and must not contain more than 5 kg of elemental fluorine. They must be labeled with the toxic-product label number 6 – 1. Cylinders containing 2.2 kg and special packages of ten cylinders are available from COMURHEX.

In the United States, fluorine is supplied by Air Products and Chemicals as a mixture of 10 % F_2 in nitrogen. Liquid F_2 was available in the 1960 s in tank trucks containing up to 2270 kg of fluorine. The inner steel shell of the tank contained the liquefied product, the intermediate stainless steel shell was filled with liquid nitrogen, and the outer shell was filled with an insulating powder.

6. Environmental Protection and Disposal of Fluorine

In laboratories or in small fluorination units, a soda – lime tower is usually sufficient for destroying waste fluorine. Suitable methods for the disposal of fluorine and hydrogen fluoride contained in gaseous effluents of fluorine-production plants have been reported [28].

Liquid effluents coming from electrolysis, compression, or purification units contain dilute hydrofluoric acid, which is generally disposed of in a lime neutralization system.

Several methods for fluorine disposal have been described in the literature. Their aim is to convert fluorine to less active and less toxic materials. The reaction of fluorine and carbon to form tetrafluoromethane has been investigated. Although several authors report that the reaction is sometimes explosive [74], others consider the disposal of fluorine by reaction with charcoal satisfactory [29], [75]. TURNBULL et al. [76] claim that the best method (Du Pont) consists of injecting fluorine into the flame of a natural-gas burner. The burner operates with propane or butane and a deficiency of air; water and caustic scrubbers are added to the system to remove the hydrogen fluoride formed by the reaction:

$$C_3H_8 + 10F_2 \longrightarrow 3\,CF_4 + 8\,HF$$

In the ICI process, waste fluorine is scrubbed in spray towers by reaction with 10 % caustic potash solution; the contact time and alkali concentration must be adjusted to avoid the formation of oxygen fluorides [29].

At present, in the COMURHEX process, waste fluorine is reacted with sulfur. Sulfur hexafluoride, oxyfluorides, and lower fluorides of sulfur are obtained; the hydrolyzable compounds are treated in an aqueous caustic scrubber; inert gases are vented to the atmosphere.

Hydrogen and fluorine produced in electrolytic cells are contaminated with a mist of fine solid particles of electrolyte; in addition, the concentration of hydrogen fluoride in the gas produced is ca. 5 – 10 vol %. The entrained electrolyte is removed by steel entrainment separators (American plants) or by an electrostatic precipitator using a nickel wire at a potential of 15 000 V (French plant [34]). Hydrogen fluoride contained in fluorine is partially removed

by condensation at −80 °C; if a low level of contamination is required (<0.02 vol %), sodium fluoride tray absorbers are used as a secondary absorption system [34]. Sodium fluoride traps are very efficient for removing HF, forming NaF · HF [*1333-83-1*]. The absorbent is regenerated by heating. In the past, HF-containing hydrogen was vented directly to the atmosphere. At the present time, HF is usually removed by condensation. After that, the gas is, if necessary, scrubbed with water or caustic solution before being vented. If may also be burned (Union Carbide Nuclear, 1962 [77], and COMURHEX, 1986).

7. Uses and Economic Aspects

Elemental fluorine is necessary to prepare the highest oxidation state fluorides, because of the combination of its oxidizing power and its fluorinating abilities. For many applications, especially in organic chemistry, milder or more specific fluorinating agents are required; these compounds are prepared from elemental fluorine. The element is also needed for specific new applications such as the synthesis of graphite fluorides, but its main application is in the field of nuclear energy [78]. All of these syntheses proceed by exothermic reactions, and temperature control is frequently necessary. Most experiments require the use of special metallic equipment (see 5). Preparative methods on the laboratory scale were reviewed [70].

Economic Aspects. The world's production of elemental fluorine, except for countries with planned economies, is concentrated in seven countries with an overall capacity of ca 17 000 t/a:

Canada Eldorado Nuclear
Federal Republic of Germany Kali Chemie
France COMURHEX
Italy Montedison
Japan Daikin Kogyo Co., Kanto Denka
Kogyo Co., Asahi Chemicals
U.K. British Nuclear Fuels, Imperial Smelting Corp.
U.S.A. Allied Chemicals, Kerr McGee, Air Products and Chemicals

Most of the elemental fluorine produced is used in two areas: (1) manufacture of 18 000 – 21 000 t/a of UF_6 [*7783-81-5*], corresponding to 6000 – 7000 t of F and (2) manufacture of 5100 – 7700 t/a of SF_6 [*2551-62-4*], corresponding to 4000 – 6000 of F. Approximately 2000 t/a are required for miscellaneous applications.

The price of elemental fluorine is estimated at $ 5 – 8 per kg, but, because of difficulties in storage and handling, the price is much higher when F_2 is supplied in cylinders. To avoid these problems, units for elemental fluorine production are integrated into SF_6 or UF_6 units.

Production of Uranium and Sulfur Hexafluorides. Elemental fluorine was used on a large scale for the first time during World War II: separation of the isotopes of natural uranium was carried out by a diffusion process involving uranium hexafluoride vapor. Fluorinated oils, greases, and polymers were needed in the associated technology. The main effort in fluorine chemistry was concentrated in the war years, but there has been continuing activity because of the peaceful application of fission processes.

Elemental fluorine is essential in the final step of processing uranium ores to produce uranium hexafluoride. UF_4 [*10049-14-6*] is first produced by the reaction of UO_2 [*1344-57-6*], and HF, and UF_6 is then prepared exclusively by the action of F_2 on UF_4:

$$UF_4 + F_2 \longrightarrow UF_6$$

Two techniques (flame reactor, fluidized beds) are used to carry out this reaction [79] (→ Uranium , Uranium Alloys, and Uranium Compounds).

Fluorine is also used to produce sulfur hexafluoride by direct combination of the elements (→ Fluorine Compounds, Inorganic, Chap. 6.1.1.).

Production of Fluorinating Agents. Chemists can now use a large variety of fluorinating compounds, some of them almost as reactive as fluorine (ClF_3, KrF_2, ...), others only mild fluorinating agents (IF_5). Only

ClF_3, BrF_3, BrF_5, and IF_5 are of industrial importance (→ Fluorine Compounds, Inorganic, Chap. 6.5.).

The great oxidizing strength of elemental fluorine is necessary to prepare high oxidation state fluorides such as CoF_3. Sometimes ClF_3 or BrF_3 are used instead of F_2 because they are easier to store and handle; however, these halogen fluorides may form stable adducts that are difficult to decompose.

Other compounds, *solid fluorine carriers*, are useful in organic syntheses. They are composed of elements with two possible oxidation states: Co(III)/Co(II), Ag(II)/Ag(I), Ce(IV)/Ce(III), Pb(IV)/Pb(II). The most widely used is CoF_3; this releases part of its fluorine in the free form when the temperature is raised to 300 – 400 °C,

$$2\,CoF_3 \longrightarrow 2\,CoF_2 + F_2$$

CoF_3 is regenerated by the reverse reaction [79].

Production of Graphite Fluoride. The name *graphite fluorides* is assigned to nonstoichiometric solid fluorocarbons with the general formula CF_x $(0 < x \leq 1.24)$. The structure of two of these intercalation compounds is known, corresponding to simple F/C ratios: CF [*11113-63-6*] or $CF_{0.5}$ [*71183-38-5*]. The general properties of these compounds have been reviewed [80–82]. Graphite fluorides are prepared by direct fluorination of various carbons at 300 – 600 °C [83]. The chemical composition and crystal structure strongly depend on the reaction temperature and the crystallinity of the starting carbons.

Minor Uses. Propulsion systems employing fluorine as a rocket-fuel oxidizer have been suggested; the abandonment of this is due to the difficulties involved in storage and handling of liquid fluorine and to pollution problems, since the reaction of F_2 with hydrogen-containing materials forms hydrogen fluoride [84].

The possible use of fluorine for the reprocessing of nuclear fuels has been investigated [85], but these studies have not yet gone beyond the pilot level [79]. This fluoride volatilization method is also called the *dry process.*

The fluorination of tungsten and rhenium forms volatile hexafluorides used in chemical vapor deposition (CVD): the thermal decomposition of WF_6 [*7783-82-6*] and ReF_6 [*10049-17-9*] form highly pure metal coatings on metallic or nonmetallic substrates [86].

Fluorine is also used to prepare NF_3 from NH_3 or $NH_4F \cdot HF$, to etch silicon [87], to produce solvent-resistant polyolefin containers [88], and to improve moisture transport and soil release of synthetic fibers (polyamide, polyester, polyolefin, polyacrylonitrile fibers) [89–91].

Elemental fluorine or fluorine diluted with nitrogen or helium can be used in preparative organic chemistry for the synthesis of highly fluorinated molecules. In this case, the lack of selectivity is not a major problem [92].

1. Hydrofluoric Acid

Hydrofluoric acid [*7664-39-3*], M_r = 20.01, has been known since the end of the eighteenth century as a product capable of attacking glass. The anhydrous acid was obtained by Fremy from potassium bifluoride in 1856. However, the uses of hydrofluoric acid did not become truly diversified and developed until 1930, with the manufacture of aluminum fluoride and synthetic cryolite for the aluminum industry, the first production of fluorocarbons, and the pickling of stainless steels. From 1940 on, hydrofluoric acid has been used for the production of uranium fluorides and as an alkylation catalyst in gasoline production. Industrial growth brought the world production of hydrofluoric acid to the level of 1×10^6 t at the beginning of the 1970 s. Then stagnation set in, a state that has lasted up to the present, because of the reductions in use required by environmental protection and the decrease in certain economic activities.

Hydrofluoric acid is a colorless liquid boiling at 19.5 °C at atmospheric pressure [1–3]. It is characterized by special physical properties resulting from the association of HF molecules by means of hydrogen bonds. It is also characterized by chemical reactivity and toxicity, which make it dangerous. All industrial hydrofluoric acid production starts from fluorite. Processes based on the recovery of fluorosilicic acid from phosphate rock have not yet gone beyond the development stage.

1.1. Physical Properties

1.1.1. Anhydrous Hydrofluoric Acid (AHF)

Regardless of physical state–solid, liquid, or gas–HF molecules tend to associate by means of hydrogen bonds:

– FH – FH –

In the solid state, these bonds form continuous zigzag planar chains [4]. Shorter and less rigid chains are present in the liquid [5]. The association of the HF molecules in the gaseous state has attracted the largest number of studies [1–3], [6–13].

Equilibria are established between the molecules HF, $(HF)_2$, $(HF)_3, \ldots$, $(HF)_n$ [8]. These equilibria are governed by the temperature (Fig. 1A [7]) and pressure (Fig. 1B [2], [14]). At the boiling point under atmospheric pressure, the average degree of association is 3.74 [1], corresponding to an average molecular mass M_r = 74.9. At atmospheric pressure, hydrofluoric acid vapor is completely depolymerized only above 100 °C.

This molecular association also affects certain physical properties, such as the boiling point and density, and also the variation of these properties with temperature and pressure. The enthalpy of polymerization is $\Delta H = -25 \pm 4$ kJ/mol [2], [10], [11], [15], [16]. This should be taken into consideration both in the calculation of the amounts of heat to be supplied for superheating hydrofluoric acid vapors and in the calculation of exchange surfaces for desuperheating these same vapors.

The principal physical properties of anhydrous hydrofluoric acid are listed in Table 1. The vapor pressure is shown as a function of temperature in Figure 2 [1].

1.1.2. Aqueous Solutions

Aqueous hydrofluoric acid solutions are colorless. They fume in air when their concentration is higher than 40 %. The specific heat of solution is 834 J for a 50 % solution and 160 J for an infinite dilution of one gram of liquid HF in water at 25 °C [25].

The principal physical properties–density [26], melting point [27], boiling point, and liquid – vapor composition [28]–are shown as func-

1.2. Chemical Properties

Hydrofluoric acid is characterized both by the stability of its molecule, which, with a dissociation energy of 560 kJ, is classified among the most stable diatomic molecules, and by its reactivity.

Hydrofluoric acid has a special affinity for oxygen compounds. It reacts with boric acid to form boron trifluoride, silica and silicates to give SiF_4 and fluosilicic acid, sulfur trioxide and sulfuric acid to form fluorosulfonic acid. The last reaction demonstrates the dehydrating power of anhydrous hydrofluoric acid.

Liquid hydrofluoric acid is a much studied nonaqueous ionizing solvent [30]. It is a strong acid in the Brönsted – Lowry sense, which gives it a catalytic activity in alkylation, isomerization, and polymerization reactions. In aqueous solution, hydrofluoric acid is a weak acid, with an activity comparable to that of formic acid.

Hydrofluoric acid is used in organic chemistry as a fluorinating agent in substitution reactions with aliphatic halides and in addition reactions with unsaturated compounds.

1.3. Manufacture

The industrial processes for the manufacture of anhydrous hydrofluoric acid are all based on the action of sulfuric acid on fluorite. However, phosphate rock, which contains fluorapatite, $CaF_2 \cdot 3\ Ca_3(PO_4)_2$, constitutes the most important natural reserves of fluorine. In fact, this ore, which is used all over the world for the manufacture of phosphoric acid, contains between 3 and 4 wt % of fluorine. The reserves are five times greater than the proven reserves of fluorite.

In the treatment of phosphate rock with sulfuric acid to produce phosphoric acid, the fluorine can be recovered in the form of dilute fluosilicic acid solution. Numerous investigations have been carried out to develop processes for the production of anhydrous hydrofluoric acid from fluosilicic acid solutions. These processes, none of which has yet undergone industrial development, are still of undeniable potential interest.

1.3.1. Fluorite Processes

Fluorite is attacked by sulfuric acid at temperatures between 100 and 300 °C. The concentration of sulfuric acid must be between 98 and 99 wt %. More dilute acid leads to increased reactor corrosion, while more concentrated acid promotes the formation of fluorosulfonic acid, HSO_3F, which would have an unfavorable effect on the reaction kinetics [31].

Acid-grade fluorspar with a grain size below 150 µm is used; CaF_2 content should be above 97 %. Main impurities:

SiO_2	1 % max
S (sulfides)	0.05 % max
$CaCO_3$	1 % max
$Al_2O_3 + Fe_2O_3$	1.5 % max
H_2O	0.1 % max

Since fluorspar is generally the more expensive of the two starting materials, a slight excess

of sulfuric acid over the stoichiometric ratio is used to ensure maximum conversion of fluorite. The unreacted raw materials are entrained by the calcium sulfate.

The main reaction

$$CaF_2 + H_2SO_4 \longrightarrow 2\,HF + CaSO_4$$

is accompanied by a number of secondary reactions:

$$SiO_2 + 4\,HF \longrightarrow SiF_4 + 2\,H_2O$$
$$CaCO_3 + H_2SO_4 \longrightarrow CaSO_4 + CO_2 + H_2O$$
$$Fe_2O_3 + 3\,H_2SO_4 \longrightarrow Fe_2(SO_4)_3 + 3\,H_2O$$
$$Al_2O_3 + 3\,H_2SO_4 \longrightarrow Al_2(SO_4)_3 + 3\,H_2O$$
$$MS + H_2SO_4 \longrightarrow MSO_4 + H_2S$$

The sulfuric acid is also reduced by the steel reactor walls:

$$Fe + 2\,H_2SO_4 \longrightarrow FeSO_4 + SO_2 + 2\,H_2O$$

The action of sulfuric acid on fluorspar therefore produces:

1) a gas phase containing hydrofluoric acid, with SiF_4, H_2O, SO_2, H_2S, and CO_2 as the main impurities
2) a solid phase consisting of calcium sulfate, containing the unreacted raw materials and iron and aluminum sulfates as the main impurities.

The reaction is heterogeneous and endothermic. These two characteristics determine the technology of all industrial reactors. The nature of the reaction medium changes during the course of the reaction, and shows that an industrial reactor must necessarily include effective stirring:

Extent of reaction	Reaction medium
0 – 40 %	liquid, pasty, then sticky and corrosive
40 – 70 %	powdered
70 – 80 %	pasty, sticky, and corrosive
80 – 100 %	powdered

The heat liberated by the secondary reactions represents less than 10 % of the heat required by the endothermic main reaction, which is close to 100 kJ for 2 mol HF at 160 °C. A supply of heat is therefore necessary for good development of the reaction of sulfuric acid with fluorspar.

The main industrial reactors can be grouped into five categories.

Simple Rotary Furnace. The two raw materials are fed into one end of the rotary furnace, and calcium sulfate is removed from the other end. This is a cocurrent reactor. The gas phase is generally discharged close to the inlet. The heat supply is provided by circulation of combustion gases in a double jacket, possibly with preheating one or both raw materials. In a Du Pont process, the heat is supplied by introducing part of the sulfuric acid in the form of a mixture of sulfur trioxide and steam [32].

The reliability of this type of reactor is based on effective agitation of the reaction mixture and on good protection against corrosion. The specific devices have not been described.

Rotary Furnace with Premixer. Developed by Buss (Fig. 4), the special co-kneader premixer ensures an intimate mixing of the raw materials. At the exit of the premixer, the extent of reaction is close to 30 %. The corrosion at the entrance to the rotary furnace is significantly reduced; however, it is not eliminated, and the dangers of crust formation on the furnace walls remain.

Figure 4. Premixer-rotary furnace [33]
a) Buss prereactor; b) Main reactor

Rotary Furnace with Prereactor [34]. Sufficient heat supply and residence time allow the conversion rate to reach 40 – 50 % at the exit of the prereactor, which supplies a powdered reaction mixture to the furnace. The furnace must, however, still contend with the second corrosive, crust-forming phase. Scraping devices combined with anti-corrosion linings are therefore necessary, or furnaces must be of large

size to permit the retention of a large volume of reaction mixture.

Rotary Furnace with Recycle [35]. The furnace is directly supplied with fluorspar and sulfuric acid, but an internal device removes a suitable quantity of mixture at the end of the reaction, in the vicinity of the outlet, and recycles it to the furnace head. The throughputs are selected so that the composition of the reaction mixture in the furnace head corresponds to a conversion rate of 80 %, and the dangers of corrosion and crust formation no longer exist. However, the furnace must be large to ensure sufficient residence time because of the high recycling rate.

Rotary Furnace with Recycle and Prereactor [36]. Combination of the two devices just described leads to units with especially high productivity.

Treatment of the Gases. The crude gas-phase hydrofluoric acid discharged from the reactor contains

hydrofluoric acid
entrained fluorite and calcium sulfate dusts
impurities heavier than HF (H_2O, H_2SO_4 as vapor and bubbles)
impurities lighter than HF (SiF_4, CO_2, SO_2, H_2S, air)

When the temperature of the gas drops to 60 – 70 °C, solid sulfur forms,

$$SO_2 + 2\,H_2S \longrightarrow 3\,S + 2\,H_2O$$

Initially, gas treatment consists of removing the solid particles and heavy impurities by one of two schemes. Scheme one:

Separation of the solid particles in a cyclone or coke box,
Separation of the heavy impurities in a 60 °C precondenser and recovery of 70 % hydrofluoric acid solution rich in sulfuric acid, which can be recycled to the furnace after the addition of oleum.

Scheme two:

Separation of dust and water in a washing column sprayed with sulfuric acid
Reconcentration of the wash acid by addition of oleum.

In a second stage, the gases are cooled to condense crude hydrofluoric acid, which must be purified by distillation (generally two columns). Finally, in a third stage, the noncondensable gases saturated with HF are washed before discharge to the atmosphere. This washing generally includes a column sprayed with sulfuric acid, which recovers the hydrofluoric acid, followed by a column sprayed with water, which recovers SiF_4 as fluosilicic acid solution.

Treatment of the Calcium Sulfate. The reaction of sulfuric acid with fluorite produces ca. 3.7 t of calcium sulfate per tonne of hydrofluoric acid manufactured. This byproduct is orthorhombic anhydrite, crystallographically identical to natural anhydrite. It can be used in cement to control the settling rate. It can also be converted to a material usable in building, mining, or road construction. However, these applications have been developed only in Germany and Japan. Everywhere else, economic conditions do not permit utilization of the calcium sulfate, which must be discarded.

1.3.2. Fluosilicic Acid Processes

The solutions containing 15 – 20 % of fluosilicic acid that are recovered in the reaction of phosphate rock constitute the raw material of all proposed processes.

Hydrolysis of SiF_4. High-temperature hydrolysis in a flame reactor, a process initially studied by Reed [37], consists of concentrating the fluosilicic acid solution to 30 %, vaporizing this solution according to reaction

$$H_2SiF_6 \longrightarrow SiF_4 + 2\,HF$$

and hydrolyzing SiF_4 in an air – hydrogen or air – hydrocarbon flame,

$$SiF_4 + 2\,H_2O \longrightarrow SiO_2 + 4\,HF$$

The by-product silica is usable. The hydrofluoric acid is collected as a dilute solution. Concentration with sulfuric acid yields anhydrous

hydrofluoric acid. The diluted sulfuric acid solutions are used for the treatment of phosphate rock.

Controlled hydrolysis of SiF_4 can be used to increase the concentration of the initial fluosilicic acid solution:

$$3\,SiF_4 + 2\,H_2O \longrightarrow 2\,H_2SiF_6 + SiO_2$$

After separation of the silica, the concentrated solution can be vaporized and decomposed to SiF_4 and HF. After the absorption of HF in a selective solvent, SiF_4 is recycled to the hydrolysis stage. Distillation regenerates the selective solvent and produces anhydrous hydrofluoric acid. Buss [38] recommends the use of a polyglycol as the selective solvent. Concentrated cold sulfuric acid is also recommended [39].

In another process claimed by Stauffer and Tennessee Corporation [40], [41], decomposition of the concentrated fluosilicic acid solution is achieved by the action of cold sulfuric acid. Under these conditions, only SiF_4 is released into the gas phase, and can therefore be directly recycled to the hydrolysis stage, while HF remains in solution in sulfuric acid diluted to 60 %. The HF – H_2SO_4 separation is carried out by distillation or stripping.

Alkaline Method. The treatment of H_2SiF_6 solutions with NH_3, the alkaline method, precipitates silica in a solution of ammonium fluoride:

$$H_2SiF_6 + 6\,NH_3 + (n+2)\,H_2O \longrightarrow SiO_2 \cdot n\,H_2O + 6\,NH_4F$$

After separation of the silica, the ammonium fluoride solution is concentrated by evaporation and decomposed to produce the bifluoride, NH_4HF_2, and ammonia.

Several processes have been proposed for the production of hydrofluoric acid from ammonium bifluoride. Goulding Chemicals [42] treats NH_4HF_2 with NaF to form sodium bifluoride, $NaHF_2$, which is then decomposed to NaF and HF. Du Pont [43] proposes the treatment of ammonium bifluoride with sulfuric acid at 180 °C to liberate hydrofluoric acid and form ammonium bisulfate.

Reaction of Na_2SiF_6, K_2SiF_6, Li_2SiF_6, or $CaSiF_6$ with HCl at temperatures between 350 and 600 °C is another method proposed to produce hydrogen fluoride [44].

None of these processes has been used industrially. However, economic studies show that the processes based on the hydrolysis of SiF_4 could compete with the processes for the manufacture of anhydrous hydrofluoric acid from fluorite, but with one restriction: these processes must necessarily be used at the sites of phosphoric acid production.

In addition, technological problems probably remain to be solved, because of the highly corrosive nature of the reaction media.

1.3.3. Corrosion-Resistant Materials

In industries producing or consuming hydrofluoric acid, material selection must take into account the acid concentration, temperature, and nature of the impurities present in both the acid and the material. Guides to selection are given in [45–47]. Nevertheless, material selected should be tested under the actual conditions of use: any error in the selection of the materials can affect not only the reliability but also the safety of the plant.

Metals. Carbon steel is commonly used with liquid or gaseous anhydrous hydrofluoric acid up to 100 – 150 °C. Carbon steel is passivated by the formation of a layer of iron(III) fluoride. Since erosion of this protective layer increases the corrosion rate, the flow rate of liquid acid in contact with a carbon steel wall should be limited to 1.5 m/s. The corrosion of carbon steel produces hydrogen, and may thereby have unexpected consequences:

- formation of an explosive air – hydrogen mixture in the dome of a storage tank
- appearance of blistering on the inner surface of the metal sheets used for storage and transport of hydrofluoric acid [48]
- embrittlement of the steel, which may, for example, involve the rupture of bolts.

The use of silicon-containing cast iron is prohibited. Silica-free cast iron cannot be recommended, because of its porosity and the danger of blistering.

Austenitic or nickel – chrome steels show no better resistance to anhydrous hydrofluoric acid than carbon steels. In particular, they must not be used at temperatures exceeding 150 °C. Monel

metal, nickel, and Inconel can be used in the presence of gaseous hydrofluoric acid up to 600 °C.

Pure aluminum shows good resistance to corrosion by anhydrous HF. However, aluminum should be selected only after tests carried out under the planned conditions of use.

The possibility of using metals in contact with aqueous hydrofluoric acid are limited. Only platinum is unattacked up to the boiling point of the solutions, regardless of their concentration. Carbon steel can be used at ambient temperature for solutions with a concentration ≥70 %. Copper is quite resistant to solutions with concentrations >60 %, up to their boiling points, provided that the flow rate is limited to 1.5 m/s. Copper is sometimes used in the construction of distillation columns for the production of anhydrous hydrofluoric acid.

Monel metal is more resistant than nickel and Inconel to solutions with concentrations ≥50 % at ambient temperature. Titanium and tantalum are strongly attacked by hydrofluoric acid, regardless of its concentration.

Ceramics. Materials containing silica are attacked by HF even in dilute solution and at low temperature.

Graphite and alumina show good resistance to solutions with concentrations <60 % up to their boiling points. Synthetic sapphire glasses maintain their transparency in contact with hydrofluoric acid.

Plastics. Polyethylene, polypropylene, and poly(vinyl chloride) show good resistance to dilute solutions containing up to 50 % of HF at ambient temperature. Polytetrafluoroethylene (PTFE) shows good resistance to anhydrous hydrofluoric acid and to its aqueous solutions. However, PTFE is not completely impermeable to hydrofluoric acid. If this material is used in a protective layer, sufficient thickness must be provided. Poly(vinylidene difluoride) (PVDF) can be used for solutions with concentrations <60 %, up to their boiling points.

Synthetic and natural rubbers are generally attacked by hydrofluoric acid. However, certain grades of ebonite are used at ambient temperature as a lining for solutions with concentrations <50 %.

1.3.4. Specifications and Analysis

Commercial anhydrous hydrofluoric acid is a highly pure product. The following standard analysis is representative of the average quality delivered by the principal producers:

HF	99.9 % max
H_2O	0.02 %
H_2SO_4	0.01 %
SO_2	0.005 %
H_2SiF_6	0.01 %

Hydrofluoric acid is also marketed in 70 % and 50 % aqueous solutions. The analytical methods for the anhydrous acid are standardized:

H_2O	ISO 3699	Karl Fischer method
H_2SO_4	ISO 3138	titrimetric method
SO_2	ISO 3702	iodometric method
H_2SiF_6	ISO 3701	photometric method with reduced molybdosilicate

1.4. Storage and Transport

The storage conditions for anhydrous hydrofluoric acid or its solutions are subject to regulation. In Europe, the European Technical Fluorine Committee [49], which includes the principal hydrofluoric acid producers, has established recommendations relating to storage equipment: construction materials, conditions of calculation, thermal insulation, supporting device, filling level, valves, safety valves, retaining tank, inspection, etc.

Anhydrous hydrofluoric acid and its aqueous solutions are subject to national and international regulations relating to the transport of hazardous materials, e.g., for transport by railroad (RID) and by road (ARD) in Europe, and the international regulations for transport by sea (IMDG code) and air (IATA).

These regulations specify the types of authorized packaging, the filling levels, the required safety devices, labeling, and traffic prohibitions. For example, the transport of anhydrous hydrofluoric acid by air is prohibited.

1.5. Toxicology and Occupational Health

In humans, hydrofluoric acid causes lesions of the respiratory system, through inhalation of vapor, and of the skin by direct contact [50], [51].

The inhalation of HF vapors causes a respiratory insufficiency that can range from simple irritation to acute pulmonary edema. The renal function can also be affected [51]. The presence of HF vapors in the air can be detected by smell, with the olfactory limit varying between 0.03 and 0.11 mg/m^3, depending on the individual. The permissible concentration limits for an exposure time exceeding eight hours vary between 0.5 and 2.5 mg/m^3, depending on the country.

An environment containing 50 mg of HF per m^3 of air is dangerous. In fact, while tolerable for one minute, it must be considered as an upper limit for a five-minute exposure and may have fatal results if the exposure is continued for more than 30 minutes. A conscious person is not able to remain for 30 minutes in an atmosphere so irritating to nose and eyes, but the danger is real for an unconscious person.

Because of the seriousness of the risk to skin from hydrofluoric acid [52], [53], the safety instructions furnished by all producers of hydrofluoric acid must be strictly followed in any handling of hydrofluoric acid. The safety equipment, gloves, safety glasses, boots, moisture-proof coveralls, breathing apparatus, and showers must be maintained in good condition.

An accident caused by hydrofluoric acid, even if it appears minor, must always be treated as a serious accident requiring the rapid intervention of competent medical staff. But it is primarily through the speed with which first aid is administered that the severity of the accidents can be considerably reduced. The rules are simple: victims of inhalation accidents must be evacuated from the contaminated areas as rapidly as possible, and burns caused by sprays must be washed with copious amounts of water, starting immediately and continuing for 15 minutes.

1.6. Economic Aspects and Uses

Table 2 shows the hydrofluoric acid production capacities of the Western world in 1982. No information concerning the production of hydrofluoric acid in the Eastern bloc countries has been published.

Table 2. Hydrofluoric acid production capacities (Western countries, 1982)

Region or country	Capacity (1000 t)
North America *	430
United States	232
Canada	106
Mexico	92
Western Europe *	339
France	98
Italy	80
Federal Republic of Germany	78

Spain	25.5
Netherlands	5
Greece	3.5
Japan *	63
Others (Tunisia, Australia, Republic of South Africa, Argentina)	28
Total	*860*

* Reproduced with permission from [54].

The two main uses, which represent more than 75 % of the total consumption of hydrofluoric acid, are (1) the manufacture of fluorocarbons and (2) the manufacture of aluminum fluoride and synthetic cryolite for the aluminum industry. However, these two applications have been subject to restrictions imposed by environmental protection for the last 10 to 15 years.

The most important fluorocarbons are chlorofluoromethanes 11 (CCl_3F), 12 (CCl_2F_2), and 22 ($CHClF_2$), and chlorofluoroethanes 113 ($CCl_2F-CClF_2$), 114 ($CClF_2-CClF_2$), and 115 ($CClF_2-CF_3$), all produced by the action of hydrofluoric acid on the corresponding chlorinated hydrocarbons. They are used as aerosol propellants, refrigerating fluids, industrial degreasing solvents, blowing agents for polyurethane, polystyrene, or polyolefin foams, and as raw materials for the manufacture of fluorinated polymers (polytetrafluoroethylene).

The restrictions concern chlorofluoromethanes 11 and 12 used as aerosol propellants. The measures were taken initially in the United States and then in Europe after the publication in 1974 of a hypothesis of Molina and Rowland [55] that the molecules of CFM 11 and 12 undergo photochemical reactions in the upper atmosphere to release chlorine atoms,

which would be capable of causing decomposition of the stratospheric ozone. The disappearance of this ozone layer would lead to an increase in the UV radiation reaching the earth's surface, which would have extremely harmful ecological consequences.

Despite numerous studies, this hypothesis has been neither confirmed nor refuted. The restrictions on the use of fluorocarbons aerosol propellants remain. As far as other applications are concerned, however, the major countries have not made any definitive, clear decisions [56].

Aluminum fluoride and synthetic cryolite are constituents of the fused alumina bath from which aluminum is produced by electrolysis. These compounds act only to lower the melting point of the bath, and the consumption is mostly losses to the atmosphere. Mainly environmental pressure has reduced the consumption, in terms of HF, from 35 kg/t of aluminum in 1960 to less than 25 kg/t of aluminum at the present. Over the long term, this market for hydrofluoric acid may be reduced by the development of aluminum production processes that do not involve any fluorine products, such as an Alcoa process based on the electrolysis of aluminum chloride.

The other applications of hydrofluoric acid are:

1) Pickling of stainless steel sheets. Hydrofluoric acid (aqueous 70 % solution) is used for certain grades of stainless steel at the rate of 10 kg HF/t steel.
2) Manufacture of UF_6. Hydrofluoric acid is used to produce UF_4 from U_3O_8; UF_4 is then converted to UF_6 with fluorine, which is obtained by electrolysis of anhydrous hydrofluoric acid.
3) Catalysis. Alkylation processes converting light olefins and isoparaffins to gasoline can be catalyzed by H_2SO_4 or anhydrous HF [57]. These processes have been developed primarily in the United States. The hydrofluoric acid consumption is ca. 2 kg/m^3 of alkylate.
4) Engraving, glass polishing, polishing of electronic silicon.
5) Manufacture of various fluorides, such as NaF or BF_3.

2. Calcium Fluoride

Fluorspar is a calcium fluoride [*7789-75-5*] ore, whose deposits are distributed over all five continents.

Crystals of fluorite were used in antiquity for the manufacture of ornamental cups and vases. The flux properties, to which fluorspar owes its name, have been known since the sixteenth century. The first mines were started up at the end of the nineteenth century in England, and then in the United States, to meet the requirements of the iron and steel industry (Bessemer and Martin processes). Later on, the electric furnace and, above all, the basic oxygen furnace, caused fluorite consumption to increase further.

In parallel, the chemical industry, using hydrofluoric acid, produced synthetic aluminum fluoride and cryolite for the aluminum industry and the fluorocarbons. Fluorspar is the only fluorine raw material used to manufacture hydrofluoric acid.

The other uses of fluorspar (manufacture of glasses, enamels, and welding fluxes) use only small quantities of ore.

World fluorite production has been at a ceiling level of five million tonnes per year since 1975. Investigations to develop a calcium fluoride (or hydrofluoric acid) manufacturing process starting from the fluosilicic acid (phosphoric acid byproduct) have not yet led to any industrial process.

2.1. Physical and Chemical Properties

The principal physical properties of calcium fluoride, M_r 78.08, are shown in Table 3. Calcium fluoride crystallizes in the face-centered cubic system, which leads to cubic or, less frequently, octahedral crystals. Crystals of pure calcium fluoride are transparent and colorless, while natural fluorite also has a broad variety of colors, ranging from red to blue. Some varieties are fluorescent in ultraviolet radiation.

Calcium fluoride forms eutectics with most metallic oxides, which makes it a useful flux. Fluorite is slightly hydrolyzed by heating in moist air above 1000 °C. It is only slightly soluble in dilute, cold acids but is attacked by hot sulfuric acid to produce hydrofluoric acid.

Table 3. Physical properties of calcium fluoride

Property	Value	Reference
Melting point *mp*	1414 °C	[58]
Heat of fusion ΔH_f	29.7 kJ/mol	[58]
Boiling point *bp*	2513 °C	[59]
Heat of vaporization ΔH_v at the *bp*	335 kJ/mol	[60]
Specific heat C_p at 25 °C	67 J/mol K	[61]
Heat of formation ΔH_f° at 25 °C	−1215 kJ/mol	[62]
Density ϱ	3.181 g/cm^3	[63]
Hardness (Mohs scale)	4	[64]
Solubility in water at 25 °C	1.7 mg/100 g H_2O	[65]
Refractive index n_D^{24}	1.43382	[66]

2.2. Production and Resources

High-purity calcium fluoride, which is used for the manufacture of special glasses and for the growth of single crystals, is obtained by the reaction of hydrofluoric acid and pure calcium carbonate.

Recovery. The locations of the fluorspar deposits are closely associated with continental rifts and lineaments (Table 4). Prospecting may be simple or difficult, depending on whether vegetation is sparse or abundant and on whether the deposit reaches the surface or not. The deposits are present either in the form of veins in vertical fissures, or in the form of horizontal beds. These two types of deposit can be exploited in surface mines or in pits and galleries.

Fluorite is generally associated with other minerals, such as quartz, barite, calcite, galena, siderite, sphalerite, or chalcopyrite (Table 5). In order to be economically workable, a deposit must have an average CaF_2 content above 20 % and, with rare exceptions, the extracted ores must be concentrated to be marketable. Selective separations are obtained in the gravity concentration processes, because calcium fluoride has a density that is generally higher than that of the minerals constituting the gangue. Preconcentration of the crushed ore can be obtained in a cone separator, using an aqueous suspension of finely ground ferrosilicon as a separation medium. The relative density of the suspension is maintained between 2.55 and 2.62 at the top of the cone and between 2.85 and 3.1 at the bottom of the cone. The ore is introduced at the top of the cone, from which the light particles are removed, while the heavier particles, rich in fluorite, drop to the bottom of the cone, where they are recovered. The ferrosilicon is recycled. A product containing 40 % of calcium fluoride is obtained from 20 % ore. Flotation then provides the different commercial grades of fluorite. Most flotation units are of the multistage type and permit the recovery of byproducts.

Table 4. Geologic fluorite deposits [67], [68]

a) *Gangue deposits*	Example
1. in magmatites	Massif Central (France)
in metamorphites	Oberpfalz (Federal Republic of Germany)
2. in clastic sedimentary rocks	Rottleberode/East Harz (German Democratic Republic)
3. in calcareous dolomite sedimentary rocks	Rosiclaire/Illinois (United States)
b) *Stratified deposits*	
1. displacements in limestone and dolomites	La Collada/Asturia (Spain)
2. marine sedimentary deposits in limestone and dolomites	Coahuila/Mexico, Cave-in-Rock Distr./Illinois (United States)
3. vulcanic sedimentary deposits	Pianciano/Latium (Italy)
c) *Deposits of different formation*	
1. occurrences and impregnations in magmatic and different rocks	Vergenoeg (Republic of South Africa)
2. deposits in carbonatites	Okoruso (South West Africa)

Production. Table 6 lists the world production of fluorite, with the contribution of each principal producing country for the years 1975 and 1980. Also listed are the reserves (calculated as finished product) considered to be economically workable in 1978.

World production has reached a ceiling of five million tons per year. Mexico is the leading producer, with over 20 % of world production.

Production at the current level would exhaust the reserves by ca. 2000. However, a shortage of calcium fluoride will be prevented by:

1) Recourse to fluorspar reserves that are not economically workable under present conditions
2) Continuation of prospecting and the discovery of new deposits
3) Production of calcium fluoride and hydrofluoric acid from fluosilicic acid.

Table 5. CaF_2 contents and accompanying minerals of fluorite in different types of deposits [67]

	Contents of CaF_2 (%)	Other minerals	Deposits
Gangue deposits	50 – 80	barite, uranium ores	Nabburg/Wölsendorf/Oberpfalz (Federal Republic of Germany)
	60 – 90	calcite, quartz (barite and sulfite missing)	Zaragoza and Rio Verde District/ San Luis Potosi (Mexico)
	60	barite, quartz	Massif Central etc. (France)
	80 – 95	sulfides (of minor importance)	La Charbonniere near Limoges (France)
	47 – 50	barite, PbS, ZnS, Cu, gravel, quartz	Rosiclaire/Illinois (United States)
	70 – 80	barite, PbS, quartz, etc.	Durham (Great Britain)
	50 – 70	3 – 25 % barite 1 – 2 % PbS	Eyam District/Derbyshire (Great Britain)
	35 – 50	little barite	Burin peninsula/New Foundland (Canada)
	18	40 % barite	Cape Breton Island/Nova Scotia (Canada)
	16 – 50	0.3 % Sn, 0.04 % WO_3, PbS, ZnS, Mo_2S, Cu gravel, etc. partly 0.2 % Be	Lost River/Alaska (United States)
	13 – 14	5 % Pb, 7 % Zn, 0.5 % Cu	San Francisco del Oro/Chihuahua (Mexico)
Stratified deposits	60 – 85	0.3 % Be (bertrandite), 10 – 12 % calcite, 5 – 10 % SiO_2	Aguachile Coahuila (Mexico)
	65 – 70, locally 80 – 90 [1]	calcite, quartz	Pico Etereo District/Coahuila (Mexico)
	20 – 60	PbS, ZnS, barite, marcasite, Cu gravel	Cave-in-Rock District/Illinois (United States)
	65 – 67	15 % Fe_2O_3 (goethite, limonite), 15 % SiO_2, little PbS	Escaro/Pyrenees (France)
	35	10 – 15 % barite, Pb/Zn sulfides, quartz	Morvan, Massif Central (France)
	20 – 40	20 – 25 % barite, 40 – 45 % SiO_2, calcite	La Collada/Asturia (Spain)
	36	40 % barite, 12 % celestite, 6 % SiO_2, little PbS, ZnS, pyrite, calcite	Djebel Zaghouan (Tunisia)
Deposits of different formation	25 – 55	13 % barite, apatite, etc.	Pianciano/Latium (Italy)
	variable Ø 15 – 20	quartz, feldspar	Buffalo, Waterberg District, Bushveld (Republic of South Africa)
	15 – 70	to 60 % Fe_2O_3 (hematite) Ø 55 % Fe_2O_3	Vergenoeg, Farm Kromdraal, Warmbad District (Republic of South Africa)

[1] These contents are unusually high for stratified deposits.

Several processes have been proposed for the manufacture of calcium fluoride from the fluosilicic acid recovered from wet phosphoric acid production, but none has been developed industrially.

The U.S. Bureau of Mines process [71] includes two stages: treatment of the fluosilicic acid solution with ammonia to precipitate filterable silica:

$$H_2SiF_6 + 6\,NH_3 + 2\,H_2O \longrightarrow 6\,NH_4F + SiO_2$$

followed by treatment of the ammonium fluoride solution with milk of lime to precipitate calcium fluoride:

$$6\,NH_4F + 3\,Ca(OH)_2 \longrightarrow 3\,CaF_2 + 6\,NH_3 + 6\,H_2O$$

The ammonia solution is recycled.

Bayer [72] and Kali Chemie [73] treat the fluosilicic acid solution with calcium carbonate suspension to a metastable solution of silica and a precipitate of calcium fluoride, which is separated by filtration and then dried.

2.3. Uses

Table 7 shows the consumption of calcium fluoride in the United States in 1980 by type of application. Ninety-eight percent of the tonnage

Table 6. World production and reserves of fluorite [69], [70] (in thousands of tonnes of commercial spar)

is consumed by two industries: the chemical industry, for the manufacture of hydrofluoric acid, and the iron and steel industry.

Table 7. Use of fluorite in the United States in 1980 (in thousands of tons) [69]

Other uses	2.1
Total	*976*

Chemical Industry. Fluorspar is the starting material for the production of hydrofluoric acid (see Chap. 1).

Iron and Steel. Fluorspar is a flux in the manufacture of steel, lowering the melting point and increasing the fluidity of the slag. Furthermore, when mixed with lime, it reduces the phosphorus and sulfur content of the metal. The use of fluorspar varies from 2 – 5 kg/t metal, depending on the type of furnace.

Fluorspar is used in the manufacture of cast iron at the rate of 6 – 8 kg/t of metal, and also in the manufacture of certain ferroalloys.

Other Uses. Fluorite constitutes 5 – 7 % of the aluminum electrolysis bath. It is used in numerous fluxes and, in particular, for welding rod coatings.

Milky or colored glasses and glass fibers can contain 10 – 20 % of fluorite. Enamels for metallic or ceramic substrates contain between 3 and 10 % of fluorite, which acts as an opacifier.

The addition of 1 % of a mixture of equal parts of gypsum and fluorspar to the raw materials for

cement reduces the clinkering temperature by 50 – 150 °C without lowering the quality of the cement [74].

2.4. Toxicology

Fluorite is not classified as a dangerous material. Nevertheless, every precaution should be taken to prevent accidental contact of calcium fluoride with an acid that would lead to the formation of hydrofluoric acid. Ingestion of fluorite dusts can be dangerous and must be avoided. For inorganic fluorides, NIOSH recommends a limiting concentration, expressed as fluorine, of 2.5 mg/m^3 air [75].

2.5. Specifications

Three commercial grades of fluorite are available:

acid-grade fluorspar (acid spar)
ceramic-grade fluorspar (ceramic spar)
metallurgical-grade fluorspar (met spar)

The specifications for acid spar are as follows:

CaF_2	97 % min
SiO_2	1 % max
S (sulfide)	0.05 % max

Users can also establish a particle size and maximum contents of $CaCO_3$, B, Be, As, and P. For ceramic spar:

CaF_2	85 – 97 %
SiO_2	2.5 – 3 % max
$CaCO_3$	1 – 1.5 % max
Fe_2O_3	0.12 % max
Pb, Zn	traces

The percentage of CaF_2 determines the grade. For met spar:

60 – 85 % CaF_2

Frequently, and particularly in the United States, the content of met spar is expressed in units of *effective CaF_2*. This content is obtained by subtracting from the CaF_2 content a value equal to 2.5 times the SiO_2 content, to take into account the fluorine-consuming reaction:

$$2\,CaF_2 + SiO_2 \longrightarrow SiF_4 + 2\,CaO.$$

Expressed as effective CaF_2, the specification is generally 70 % minimum. The content of free sulfur or sulfide is limited to 0.3 %. Maxima may also be established for lead (0.25 %) and for As, Ba, and Zn, at the level of 100 ppm. The particle size is preferably between 5 and 80 mm.

The presence of fines allows significant losses by entrainment. To avoid this, briquettes are made by agglomeration of fines with molasses acting as a binder. Numerous additives (MnO_2, Al_2O_3, $Ca(OH)_2$, feldspar, ilmenite, etc.) can be incorporated at the user's request. The shape and size of the briquettes differ: the current peach-pit type have a length of 2.5 cm. In the United States, steelmaking used 110 000 t of briquettes in 1980.

2.6. Chemical Analysis

The analytical methods for fluorite have been standardized or are in the process of standardization:

H_2O	ISO 4282	Drying at 105 °C
Fluorine	Draft ISO 5439	Willard – Winters method
SiO_2	Draft ISO 5438	Colorimetry of the reduced blue silicomolybdate complex
$BaSO_4$	Draft ISO 5437	Gravimetry
Carbonates	Draft ISO 4283	Acidimetry after release and absorption of CO_2 in sodium hydroxide solution
Sulfides	Draft ISO 4284	H_2S converted to cadmium sulfide and titrated iodometrically
Phosphorus	Draft ISO 6676	Colorimetry of the yellow phosphato-vanadomolybdate complex

Calcium can also be determined by complexometry with EDTA, boron by colorimetry with carminic acid, and arsenic by colorimetry of the red complex obtained by the absorption of AsH_3 in a solution of silver diethyldithiocarbamate in pyridine.

3. Aluminum Fluoride and Fluoroaluminates

Aluminum fluoride [*7784-18-1*] and cryolite [*15096-52-3*] are the two aluminum – fluorine compounds of industrial importance. Their main application is in baths for electrolytic aluminum production, accounting for over 95 % of their use.

For a long time, the fluorine raw material was hydrofluoric acid, but its importance has decreased considerably since 1975. Between 1975 and 1981, 20 – 25 % of the production of aluminum fluorides was based on fluosilicic acid, an effluent in the manufacture of phosphoric acid and hydrofluoric acid [76, no. 7391002 H]. This proportion should increase in the future, for the following reasons:

1) In 1985, only 40 % of the phosphoric acid units were equipped for fluosilicic acid recovery and, in all cases, 80 % of this acid was destroyed [77].
2) Fluosilicic acid recovery is easy, and the cost of the fluorine is well below that from hydrofluoric acid.
3) An estimate made in 1978 showed that the confirmed reserves of fluorine in phosphates were five times greater than those of fluorine in fluorite [78], [79].
4) The recovery of fluorine effluents of the aluminum industry will intensify under the pressure of the strict regulations for fluorine-containing wastes. Efforts between 1960 and 1981 to recycle fluorine effluents back to the electrolysis cells, reduced fluorine consumption from 35 to 24 kg/t aluminum [80]. Progress remains to be made in fluorine recovery both in phosphoric acid plants and aluminum plants.

3.1. Aluminum Fluoride

3.1.1. Properties

The only important aluminum fluoride is the trifluoride, M_r 83.98: white solid consisting of a trigonal crystal and usually forming rhombohedrous (88°49′), space group $R32D_3^7$ with 2 AlF_3 per unit cell and dimensions of $a_0 = 0.504$ nm and $\alpha = 58°31'$ [81]. Each Al atom is coordinated by six F atoms, with three Al – F distances of 0.170 nm and three of 0.189 nm. The F – F spacing is 0.253 nm. The lattice vacancies can be occupied by water molecules.

At atmospheric pressure, aluminum trifluoride does not melt but rather sublimes. The main characteristics of aluminum fluoride are shown in Table 8.

Table 8. Physical properties of aluminum fluoride

Property	Value	Reference
Sublimation point	1272 – 1278 °C	[82]
Vapor pressure P at 1000 °C	910 – 920 Pa	
Density ϱ	3.10 g/cm^3	
Heat of formation at 298 K ΔH_f°	−1489 kJ/mol	[83], [84]
Free energy of formation at 298 K ΔG_f°	−1426 to −1431 kJ/mol	[84]
Refractive index n_D	1.376	
Entropy S_{298}°	66.2 – 66.5 J/mol K	[82]

Solubility in water: the trihydrate prepared by precipitation below 25 °C has a solubility of 4.1 g/L (expressed as AlF_3). On the other hand, concentrated solutions (ca. 200 g/L) prepared and kept for 10 h at 90 – 100 °C and stirred in the presence of the solid precipitate the β form. The solution above the β form maintains a concentration close to 16 g/L, regardless of temperature.

The remarkable aspect is the stability of the supersaturated concentrated solution. When cooled abruptly from 100 to 20 °C, in the absence of solid, it can be kept for several hours at concentrations of close to 200 g/L. This stability varies with the contents of HF and AlF_3 [85].

In the presence of HF, the solubility of AlF_3 in water at 25 °C goes through a maximum of 17 wt % for an HF concentration close to 39 %, probably related to the presence of $AlF_3 \cdot 3\,HF$ (AlF_6^{3-} ion) [86]. The solubility in organic solvents is very low.

Aluminum fluoride, when heated above 250 °C in the presence of steam, undergoes partial hydrolysis:

$$2\,AlF_3 + 3\,H_2O \longrightarrow 6\,HF + Al_2O_3 \qquad (1)$$

For the dehydration of $AlF_3 \cdot 3\,H_2O$, this hydrolysis must be avoided, and the drying and calcination conditions must be appropriate.

3.1.2. Manufacture

Raw materials:

1) Partially dehydrated aluminum hydroxide, and to a lesser extent uncalcined alumina
2) Gaseous hydrofluoric acid, 100 % or diluted with air, and concentrated solutions containing 30 – 70 % of HF
3) Fluosilicic acid (20 – 30 % H_2SiF_6)

3.1.2.1. Hydrofluoric Acid Processes

Aqueous Hydrofluoric Acid Process [87]. Installations using hydrofluoric acid solution are increasingly rare. The process consists of reacting alumina trihydrate, $Al_2O_3 \cdot 3\,H_2O$, continuously or discontinuously with hydrofluoric acid solution at 80 °C until the alumina dissolves completely. The stirred supersaturated solution of AlF_3, with or without seeding, deposits $AlF_3 \cdot 3\,H_2O$, which is separated by filtration. The solid is dried and calcined in one or two stages to furnish a product containing 90 – 98 % AlF_3. The mother liquor, with a content of ca. 18 g/L of AlF_3, can be used for cryolite production.

Gaseous Hydrofluoric Acid Process. The processes using this method operate with a two- or three-stage fluidized bed [88] with gaseous hydrofluoric acid (possibly diluted) as a carrier. The alumina trihydrate reacts countercurrently, and is dehydrated and fluorinated at temperatures of 500 – 600 °C :

$$Al_2O_3 \cdot 3\,H_2O(s) + 6\,HF(g) \longrightarrow 2\,AlF_3(s) + 6\,H_2O(g)$$
$$\Delta H^0_{298} = -126\,\text{kJ/mol}\,AlF_3$$
$$Al_2O_3 \cdot H_2O(s) + 6\,HF(g) \longrightarrow 2\,AlF_3(s) + 4\,H_2O(g)$$
$$\Delta H^0_{298} = -182.7\,\text{kJ/mol}\,AlF_3$$
$$Al_2O_3(s) + 6\,HF(g) \longrightarrow 2\,AlF_3(s) + 3\,H_2O(g)$$
$$\Delta H^0_{298} = -212.1\,\text{kJ/mol}\,AlF_3$$

(The heats of reaction were obtained by using for the heat of formation of $AlF_3(s)$ the value of −1488.9 kJ reported by Kubachewski [83], which is more reliable than the values found in other references, which range from −1400 to −1510 kJ.)

The installations differ in the way the gaseous hydrofluoric acid is used. Hydrofluoric acid that is practically pure, except for small traces of SO_2 and SiF_4, is obtained by vaporization of anhydrous HF. This technique is used by numerous companies: Allied Chemical, Bayer, Kaiser, Montedison, Stauffer, and Ugine Kuhlmann before 1970.

Another method takes the HF directly at the exit of the rotary production furnace and heats it with an internal burner to furnish a mixture with one-fifth the usual HF content (approx. 200 g/m^3), which reacts directly with the fluidized alumina. This technique is more economical, because it avoids the anhydrous HF stage, but the fluidized bed reactor must be bulkier. It is used by Pechiney, the world's largest producer, with a capacity of 90×10^3 t in its plant at Salindres (France). The effluent gas, containing SiF_4 and a small amount of HF, is washed with water to produce a solution of fluosilicic acid and HF. These techniques produce a grade containing only 89 – 91 % of AlF_3. Numerous technological improvements have been made over the years [89].

3.1.2.2. Fluosilicic Acid Processes

Direct Process. For more than 25 years, aluminum fluoride has been produced throughout the world from fluosilicic acid, which originates mainly from the recovery of fluorine in the phosphate industry and to a lesser extent from the manufacture of HF from fluorite and of AlF_3 from HF. The first installation was started up in Linz, Austria, by O.S.W. (Oesterreichische Stickstoffwerke) in 1962 [90], followed by plants in Sweden, Japan, USA, former states of USSR, India, Poland, Spain, Romania, France, and the German Democratic Republic. Numerous patents have been filed, particularly by O.S.W.

The aluminum fluoride produced must meet the purity standards

$SiO_2 < 0.2\,\%$
$P_2O_5 < 0.025\,\%$

Figure 5. Simplified process flow sheet for the production of AlF_3 from H_2SiF_6 and $Al_2O_3 \cdot 3\,H_2O$
a) H_2SiF_6 storage tank; b) Reactor; c) Alumina hopper; d) Silica filter; e) Crystallizers; f) Trihydrate filter; g) Drier; h) Cooler; i) Finished product storage hopper; j) Weak mother liquor storage tank

required for aluminum electrolysis. The silica standard is easy to achieve, but the P_2O_5 standard, equivalent to a P_2O_5 : F ratio of <0.0004, is more of a challenge. The principal effort to remove P_2O_5 must be made during recovery of fluosilicic acid.

The various phases of the process for the manufacture of AlF_3 from fluosilicic acid are shown in Figure 5 [91].

Alumina trihydrate is dissolved in a batch process or less frequently in a continuous process in 15 wt % fluosilicic acid preheated to 60 °C:

$$H_2SiF_6 + Al_2O_3 \cdot 3\,H_2O \longrightarrow 2\,AlF_3 + SiO_2 + 4\,H_2O$$

The heat evolved brings the temperature of the mixture to 90 – 100 °C, and reaction is complete within 20 minutes. The precipitated silica must be easily filterable. The following parameters therefore are varied during the reaction: temperature, concentration and excess of reagents, agitation, pH. All producers have their own precise conditions. The silica is filtered off and washed on a belt filter, bucket filter, or even a centrifugal filter. The supersaturated AlF_3 solution is placed in stirred tanks maintained at 80 – 90 °C for 5 – 8 h, with or without seeding. After the crystallization of β-$AlF_3 \cdot 3\,H_2O$, this is separated on a rotary or belt filter, with or without washing of the cake.

The mother liquors contain ca. 18 g/L of AlF_3 and can be reused: (1) for dilution of the fluosilicic acid, (2) as the first washing of the silica on the filter, (3) in washing the gases of phosphoric acid and superphosphate units, and (4) in the manufacture of cryolite. The limit of recovery of these mother liquors is fixed by their P_2O_5 content, which must not exceed 100 ppm.

The moist trihydrate is dried in two stages, a method known since 1946 [92]. Since then numerous variations have been proposed, and many patent applications have been filed. In the first stage the temperature is limited to 250 °C to prevent hydrolysis (Eq. 1) and to produce a composition close to $AlF_3 \cdot 0.5\,H_2O$. This is subjected, in a second stage, to heating to 500 – 600 °C, either slowly in an indirectly heated rotary furnace or more rapidly in a fluidized bed [93]. In all cases, a calcined product containing 97 – 98 % AlF_3 is obtained, which must be protected against moist air [94].

One variation would be of interest: crystallization of a fluoride with a low degree of hydra-

tion (0.15 – 1 H_2O) with crystallization at high temperature and pressure [95].

Indirect Process. The intermediate is ammonium cryolite, $AlF_3 \cdot 3\,NH_4F$, which is manufactured by reacting aqueous ammonium fluoride

$$H_2SiF_6 + 6\,NH_4OH \longrightarrow 6\,NH_4F + SiO_2 + 4\,H_2O$$

with partially dehydrated alumina [96]:

$$12\,NH_4F + Al_2O_3 \cdot x\,H_2O \longrightarrow 2\,AlF_3 \cdot 3\,NH_4F + 6\,NH_3 + (x+3)\,H_2O \quad (2)$$

or with a solution of AlF_3:

$$3\,NH_4F + AlF_3 \longrightarrow AlF_3 \cdot 3\,NH_4F \quad (3)$$

This last reaction can be carried out in a fluidized bed [97], which produces calibrated crystals of ammonium cryolite, thus facilitating further treatment.

The manufacture of AlF_3 from ammonium cryolite can be carried out by two methods:

1) Thermal decomposition at 400 – 500 °C, liberating NH_4F:

$$AlF_3 \cdot 3\,NH_4F \longrightarrow AlF_3 + 3\,NH_4F$$

which is recycled. The difficulty is collecting sublimed NH_4F by washing.

2) Reaction with partially dehydrated alumina, liberating NH_3, which is easier to recycle:

$$2\,AlF_3 \cdot 3\,NH_4F + Al_2O_3 \cdot x\,H_2O \longrightarrow 4\,AlF_3 + 6\,NH_3 + (x+3)\,H_2O$$

These two processes are not as simple as the direct process because of the recycling of NH_4F or NH_3. The one advantage, except pointed out by the Tennessee Valley Authority (TVA) and Mekog Albatros [98]: P_2O_5 is removed during precipitation of the ammonium cryolite.

3.1.2.3. Recovery of Fluorine During Aluminum Production

The fluorine in the gases emitted by the electrolysis cells (hydrolysis of the bath or sublimation in the form AlF_3 or atmolite, $NaAlF_4$) must be recovered for economic and environmental reasons. At the present time, virtually the only recovery process being developed further involves the dry method.

Dry Method. In the dry method, classical Sandy Coarse alumina, with a BET surface area between 45 and 80 m^2/g, is used to recover the fluorine in new automated cells, cf. [99]. This alumina is injected into the circuit for collection of the cap gases [100], and 99.99 % of the hydrogen fluoride is chemisorbed within a few seconds. All particles (alumina and solid dusts) are retained in a bag or sack filter. Only neutral gases can pass through the alumina cake fixed on the bags. The alumina fluorinated in this way, which also contains some impurities, is recovered and added to the cell.

This system is presently employed in all modern cells using the Aluminum Pechiney technology: St. Jean de Maurienne, Tomago, Becancour, Karmoy, and others. Less than 1 kg HF/t of aluminum is allowed to escape.

Wet Method. In the wet method, the effluent gases of old aluminum cells are washed with ca. 20-g/L AlF_3 solution, absorbing the dilute hydrofluoric acid, to bring the solution to approximately 5 g/L of HF in one or two stages. Neutralization with alumina produces a solution containing approximately 27 g/L of AlF_3, which precipitates 11.5 g/L of $AlF_3 \cdot 3\,H_2O$. The mother liquor, containing approximately 20 g/L of AlF_3, is returned to the gas washing stage [101].

Although this acid washing technique does not retain the SO_2, its low productivity, 11.5 g of $AlF_3 \cdot 3\,H_2O$ per liter in circulation, is a disadvantage.

3.2. Fluoroaluminates

The fluoroaluminates constitute a class of products containing aluminum and fluorine that can be written in the form

$$x\,AlF_3 \cdot y\,MF$$

where $1 \leq x \leq 3$ and $1 \leq y \leq 5$; M represents an alkali or alkaline-earth metal.

Cryolite, $AlF_3 \cdot 3\,NaF$, and chiolite, $3\,AlF_3 \cdot 5\,NaF$, are the two principal minerals. However, the quantities mined do not exceed 50×10^3 t of cryolite per year.

In addition to sodium, other cations, such as Ca, Mg, Li, K, Sr, NH_4, and Li/Na combinations are known in nature. Compounds containing oxygen and OH groups in addition to Al and F also exist.

The two most important fluoroaluminates obtained by synthesis are sodium cryolite, or simply cryolite, and the intermediate, ammonium cryolite, $AlF_3 \cdot 3\,NH_4F$.

3.2.1. Cryolite, $AlF_3 \cdot 3\,NaF$

3.2.1.1. Properties

At room temperature, crystalline cryolite, M_r 209.94, is monoclinic, with a slight deviation from orthorhombic symmetry ($R = 90°\ 11'$). The space group is P21/m, with $a = 0.546$, $b = 0.561$, and $c = 0.780$ nm [102]. The physical properties are shown in Table 9.

Table 9. Physical properties of cryolite

Property	Value	Reference
Melting point *mp*	1009 – 1012 °C	
Vapor pressure *P*		
at 1000 °C	253 Pa	[103]
Density ϱ	2.97 g/cm^3	
Heat of formation ΔH_f°	−3297 kJ/mol	
Heat of fusion ΔH_f		
at 1012 °C	225 kJ/mol	
Refractive index n_D	1.339	
Entropy S_{298}°	238 J/mol K	[103], [104]
Electrical conductivity *K*		
Liquid at 1012 °C	2.82 Ω^{-1}cm^{-1}	
Solid at 400 °C	$4 \times 10^{-6}\ \Omega^{-1}$cm^{-1}	

Heating cryolite causes crystalline transformations, accompanied by changes in density and electrical conductivity [104].

Cryolite is important because it is the main constituent of the baths for aluminum production; it lowers the melting point below 1000 °C, while dissolving AlF_3, NaF, CaF_2, LiF, and the oxides Al_2O_3, MgO, TiO_2, etc. In the fused bath (65 wt % $AlF_3 \cdot 3\,NaF$) the important equilibrium expression is [105]

$$AlF_3 \cdot 3\,NaF \rightleftharpoons 2\,NaF + AlF_3 \cdot NaF$$

The properties of this bath have been often studied, especially density, viscosity, solubilities, conductivity [104], [106]. Conductivity is provided primarily by the Na^+ ions.

Cryolite has a solubility in water of 0.042 g at 25 °C and 0.135 g at 100 °C per 100 g of solution; the solubility is lower in the presence of NaF and is higher in the presence of acid [107], base, or aluminum, or iron salts [108]. If air is excluded, the melting loss at 400 °C is less than 0.5 % for natural cryolite and between 2 and 3 % for synthetic cryolites.

3.2.1.2. Manufacture

Although the specific consumption of cryolite is lower than that of aluminum fluoride in electrolytic aluminum production, and the ratio is continuously changing to AlF_3, the manufacture of cryolite continues to be the subject of new studies.

The processes developed during 1931 – 1951 have lost appeal for two reasons [109]:

1) Complexity, execution requiring several stages
2) Raw materials that are scarce or out of favor (high-silica fluorite, CO_2–H_2SO_4–$NaHCO_3$, $AlCl_3$, etc.).

Modern processes use raw materials such as HF, H_2SiF_6, $Al_2O_3 \cdot 3\,H_2O$, $Al_2O_3 \cdot x\,NaOH$, NaOH, NaCl, and Na_2SO_4. Usually, manufacture is placed close to the sources of fluorine and aluminum, to reduce costs further.

The quality of the final product has been significantly improved:

1) NaF/AlF_3 ratios close to 3, and adjustable around this value
2) high bulk densities, close to 1.5 g/cm^3
3) spherical particles, average diameter adjustable from 50 – 200 µm, which are easy to filter, wash, dry, and calcine [110], [111].

These techniques have been placed on an industrial scale by Ugine Kuhlmann.

Hydrofluoric Acid Processes. The main hydrofluoric acid processes can be summarized by the equation

$$12\,HF + Al_2O_3 \cdot 3\,H_2O \longrightarrow 2\,AlF_3 \cdot 3\,HF + 6\,H_2O$$

followed by one of the three equations

$$2\,AlF_3 \cdot 3\,HF + 6\,NaOH \longrightarrow 2\,AlF_3 \cdot 3\,NaF + 6\,H_2O$$

$$2\,AlF_3 \cdot 3\,HF + 3\,Na_2CO_3 \longrightarrow 2\,AlF_3 \cdot 3\,NaF + 3\,H_2O + 3\,CO_2$$

$$2\,AlF_3 \cdot 3\,HF + 6\,NaCl \longrightarrow 2\,AlF_3 \cdot 3\,NaFO + 6\,HCl$$

These operations are generally carried out by a batch process: after the alumina is dissolved in 40–60 % HF solution in one hour at 70 °C, cryolite is precipitated by addition of NaOH, Na_2CO_3, or NaCl. After the slurry is filtered, the solids are calcined at 600 °C in a rotary or platform furnace. These operations can also be carried out continuously in a fluidized bed to produce granular cryolite [111]. Ugine Kuhlmann put into industrial use between 1965 and 1970 another continuous, fluidized bed process (capacity 8000 t/a) using a solution of sodium aluminate from Bayer alumina production

$$12\,HF + Al_2O_3 \cdot 6\,NaOH \longrightarrow 2\,AlF_3 \cdot 3\,NaF + 9\,H_2O \quad (4)$$

The aluminate solution can be taken from the concentration stage following the filtration of alumina and contains approximately 150 g/L of Al_2O_3 and 360 g/L of NaOH (→ Aluminum Oxide). After cooling, this solution is stable and can be stored and transported without solids formation. Its cost is very attractive. This process [111] can produce calibrated cryolite with an average diameter of approximately 80 µm at the exit of a fluidized bed supplied with aluminate and 40–70 wt % hydrofluoric acid. Filtration and drying are facilitated. No dust is formed.

Fluosilicic Acid Processes [112], [113]. Fluosilicic acid, an effluent from HF and AlF_3 manufacture, and above all, from phosphate and superphosphate plants, must meet very rigorous requirements with respect to its P_2O_5 content: the cryolite produced must have a P_2O_5:F ratio $\leq$0.0004 [114]. The standard for SiO_2 is less rigorous (<0.2 %) and is easier to attain if good conditions of precipitation and filtration of the silica are provided in the course of the neutralization of the H_2SiF_6 [115].

Three processes can be distinguished: (1) NH_4F intermediate, (2) AlF_3–NaF intermediate, and (3) Na_2SiF_6 intermediate.

NH_4F Intermediate . A solution is obtained after neutralization of the fluosilicic acid with aqueous ammonia and separation of the silica

$$H_2SiF_6 + 6\,NH_4OH \longrightarrow 6\,NH_4F + SiO_2 + 4\,H_2O$$

The intermediate can be reacted with sodium aluminate:

$$12\,NH_4F + Al_2O_3 \cdot 6\,NaOH + 3\,H_2O \longrightarrow 2\,AlF_3 \cdot 3\,NaF + 12\,NH_4OH$$

This process was used as early as 1940 by I.G. Farbenindustrie at Oppau and is presently in use in two plants in former Yugoslavia [112]. The effluent ammonia solution is recycled. In a fluidized bed on a pilot-plant scale, Ugine Kuhlmann was able to verify this technique to manufacture granular cryolite [111].

The intermediate can also be reacted with alumina or with aluminum fluoride [Eqs. (2) and (3)] to produce ammonium cryolite, $AlF_3 \cdot 3\,NH_4F$, which can be transformed to sodium cryolite by reaction with sodium hydroxide:

$$AlF_3 \cdot 3\,NH_4F + 3\,NaOH \longrightarrow AlF_3 \cdot 3\,NaF + 3\,NH_4OH$$

with recycling of the ammonia solution to NH_4F manufacture. A sodium salt is more economical than sodium hydroxide:

$$AlF_3 \cdot 3\,NH_4F + 3\,NaCl \longrightarrow AlF_3 \cdot 3\,NaF + 3\,NH_4Cl$$

An ammonium cryolite stage makes is possible to remove the P_2O_5 in the NH_4F solution [98].

Manufacture from NaF and AlF_3 [116]. Two solutions are prepared from fluosilicic acid: (a) a solution of 150 g/L of AlF_3 and (b) a solution of 40 g/L of NaF obtained by neutralization of fluosilicic acid with NaOH or Na_2CO_3 and separation of the silica:

$$H_2SiF_6 + 6\,NaOH \longrightarrow 6\,NaF + SiO_2 + 4\,H_2O$$

The two solutions are mixed to obtain cryolite:

$$AlF_3 + 3\,NaF \longrightarrow AlF_3 \cdot 3\,NaF$$

The AlF_3 solution can also be the mother liquor from the filtration of $AlF_3 \cdot 3\,H_2O$ production, a means of effectively using these mother liquors, which contain 18 g/L of AlF_3 and 7 % of the fluorine yield of AlF_3 manufacture.

Na_2SiF_6 Intermediate [117]. By starting from impure fluosilicic acid, a sodium fluosilicate with a low P_2O_5 content is obtained; furthermore, Na_2SiF_6 has a higher fluorine content (61 % F) than 30 % fluosilicic acid (24 % F), which makes transport less expensive when cryolite cannot be produced where H_2SiF_6 is recovered.

A number of processes are used for the manufacture of cryolite from Na_2SiF_6 in the various countries–USA, Japan, and India. There are two principal techniques: hydrolysis with Na_2CO_3 and hydrolysis with ammonia.

The process described by Kaiser Aluminum [118] has been known since 1960. A sodium fluoride solution is prepared by treating sodium fluosilicate with Na_2CO_3 and separating silica:

$$Na_2SiF_6 + 4\,Na_2CO_3 + 2\,H_2O \longrightarrow 6\,NaF + SiO_2 + 4\,NaHCO_3$$

The resulting solution is reacted with sodium aluminate to precipitate cryolite:

$$12\,NaF + Al_2O_3 \cdot 2\,NaOH + 8\,NaHCO_3 \longrightarrow 2\,AlF_3 \cdot 3\,NaF + 8\,Na_2CO_3 + 5\,H_2O \qquad (5)$$

The sodium carbonate is recycled.

The reaction of sodium fluorosilicate with aqueous ammonia [119], after separation of the silica, produces a solution of sodium and ammonium fluorides:

$$Na_2SiF_6 + 4\,NH_4OH \longrightarrow 2\,NaF + 4\,NH_4F + 2\,H_2O + SiO_2$$

To obtain cryolite, the two fluorides are reacted either with a solution containing an aluminum salt and a sodium salt,

$$4\,NaF + 8\,NH_4F + Al_2(SO_4)_3 + Na_2SO_4 \longrightarrow 2\,AlF_3 \cdot 3\,NaF + 4(NH_4)_2SO_4$$

or with an aluminate solution

$$2\,NaF + 4\,NH_4F + NaAlO_2 + 4\,H_2O \longrightarrow AlF_3 \cdot 3\,NaF + 4\,NH_4OH + 2\,H_2O$$

In the second case, the ammonia solution is recycled.

In a process that has not gone beyond the pilot-plant stage, a mixture of solids Na_2SiF_6 and $AlF_3 \cdot 3\,H_2O$ is heated to 800 °C and to limit hydrolysis of AlF_3 and SiF_4 the mixture is impregnated with aqueous hydrofluoric acid:

$$3\,Na_2SiF_6 + 2\,AlF_3 \longrightarrow 2\,AlF_3 \cdot 3\,NaF + 3\,SiF_4 \uparrow$$

The major disadvantage is the need to convert SiF_4 to H_2SiF_6, which represents a recycling of four of the six fluorine atoms contained in the starting Na_2SiF_6 [120].

Recovery of Fluorine During Aluminum Production. *Washing of Emitted Gases.* After separation of the soots and metal oxides on a bag or electrostatic filter, the gases are washed either with water or an alkaline solution (NaOH or Na_2CO_3). In the first case, a dilute solution of hydrofluoric acid (6 – 10 g/L) is obtained. When it is treated with sodium aluminate solution [Eq. (4)] and the resulting solution crystallized in a fluidized bed, a sandy cryolite 100 – 130 µm in diameter is obtained [111]. This technique has been in use since 1960 in the Société Péchiney aluminum plant at Lannemezan (France).

In the second case, the solution obtained contains a mixture of NaF and $NaHCO_3$, which is treated according to Equation (5) with an aluminate solution to precipitate cryolite. The sodium carbonate is recycled.

Leaching of Cathode Crusts. During repair of the electrolysis cells, crusts containing fluorine and essentially all of the sodium introduced both by the alumina and the cryolite are removed. Their composition is variable: sodium – fluoride – aluminate. Treatment for recovery is not simple and rarely profitable: after crushing and grinding of the crusts, it consists of extraction with water, aqueous sodium hydroxide, and finally hydrofluoric acid, producing solutions of sodium aluminate, sodium fluorides, and dilute solutions of AlF_3 and HF [121]. By reacting these solutions alone or in the presence of hydrofluoric acid, or of alkaline gas-washing solutions, cryolite is precipitated:

$$5\,NaF + Al_2O_3 \cdot 2\,NaOH + (4\,NaF + 8\,NaHCO_3) \longrightarrow 2\,AlF_3 \cdot 3\,NaF + 8\,Na_2CO_3 + 5\,H_2O$$

$$2\,NaF + Al_2O_3 + 10\,NaOH + 2\,AlF_3 + 16\,HF \longrightarrow 4\,AlF_3 \cdot 3\,NaF + 13\,H_2O$$

The carbonate can be recycled to the leaching stage.

3.2.2. Ammonium Cryolite

Ammonium cryolite, $AlF_3 \cdot 3\,NH_4F$, is an intermediate in the production of AlF_3 (Section 3.2) and cryolite (see page 21) from H_2SiF_6.

Another role of ammonium cryolite as an intermediate, in this case in the production of anhydrous HF from H_2SiF_6, may be cited. Ugine Kuhlmann has studied all of the reactions on a prepilot stage. The process can be summarized in four equations:

$$H_2SiF_6 + 6\,NH_3 + 2\,H_2O \longrightarrow SiO_2 + 6\,NH_4F$$
$$2\,NH_4F \longrightarrow NH_4F \cdot HF + NH_3$$
$$2\,NH_4F \cdot HF + AlF_3 \cdot NH_4F \longrightarrow AlF_3 \cdot 3\,NH_4F + 2\,HF\uparrow$$
$$AlF_3 \cdot 3\,NH_4F \longrightarrow AlF_3 \cdot NH_4F + 2\,NH_4F$$

The NH_4F produced in the last reaction is recycled in the second equation. The net equation is then:

$$H_2SiF_6 + 2\,H_2O \longrightarrow SiO_2 + 6\,HF\uparrow$$

3.3. Environment Protection

Aluminum fluoride and cryolite are produced from two raw materials capable of presenting storage and handling problems: hydrofluoric and fluosilicic acids. In the manufacture of the aluminum fluorides, HF and SiF_4 may be released as a result of hydrolysis occurring during drying and calcination at 500 – 600 °C. The quantities of HF may reach 3 – 10 % of the fluorine contained.

The environmental problem is solved by washing the off-gases with water. The fluorine is recovered, or the wash water is neutralized with lime.

3.4. Specifications

The principal specifications for aluminum fluoride are as follows:

$AlF_3 \geq 90\,\%$	(quality of the product obtained from $H_2SiF_6 \geq 97\,\%$)
$Al_2O_3 \leq 10\,\%$	(quality of the product obtained from $H_2SiF_6 < 3\,\%$)
$SiO_2 < 0.2\,\%$	
$Fe_2O_3 < 0.1\,\%$	
$P_2O_5 < 0.025\,\%$	
Average diameter 40 – 60 µm.	

The principal specifications for cryolite are as follows:

$AlF_3 \cdot 3\,NaF$	$\geq$95 %
F	50 – 53.5 %
Al	13 – 15 %
Free Al_2O_3	3 – 5 %
SiO_2	$\leq$0.2 %
Fe_2O_3	$\leq$0.1 %
P_2O_5	$\leq$0.02 %
NaF : AlF_3	2.8 – 3.1

Particle size distribution: average diameter 50 – 120 µm for the calibrated particles obtained by fluidized bed crystallization, or fine powder between one and ten micrometers in size.

3.5. Chemical Analysis

The 1984 ISO catalog provides the following references to analyses of the principal constituents of AlF_3 and $AlF_3 \cdot 3\,NaF$.

	AlF_3	$AlF_3 \cdot 3\,NaF$
F	2362 – 1972	1693 – 1976
Al	2367 – 1972	2367 – 2972
		2830 – 2973
Na		Oliver and Winter, *Anal. Chim. Acta* **51** (1970) 409
Fe	2368 – 1972	
SiO_2	2369 – 1972	1620 – 1976
H_2O	3392 – 1976	
	3393 – 1976	
P_2O_5	5930 – 1979	
	6374 – 1981	

3.6. Uses

Aluminum Fluoride. Almost all of the aluminum fluoride (over 95 %) is used in electrolysis cells for the production of aluminum (15 – 20 kg per tonne of aluminum) and in cells for electrolytic aluminum refining. In the second

case, the high-purity aluminum fluoride (>97 % AlF_3) obtained by the H_2SiF_6 method is preferred.

The specific consumption of AlF_3 is increasing at the expense of that of cryolite, for the following reasons:

1) The alumina introduced into the electrolysis cells contains sodium (equivalent to 5 000 ppm of Na_2O, on the average), which is converted to cryolite in the fused bath in the presence of AlF_3.
2) The gases emitted by the cell contain sodium tetrafluoroaluminate, $AlF_3 \cdot NaF$, containing a larger quantity of AlF_3 than cryolite, $AlF_3 \cdot 3\,NaF$, requiring a make-up of AlF_3.
3) Use of a more acid bath to increase the reactivity.

The other uses of aluminum fluoride are considerably less important [122]:

glass for optical purposes, lasers, and electrical conductors
ceramics
protector of baths for the refining of light metals
welding flux
constituent of catalysts for the preparation of certain halogenated hydrocarbons

Cryolite. Cryolite is the principal constituent of the electrolysis bath for aluminum production. Nevertheless, its specific consumption (4–10 kg/t aluminum) is relatively low and is decreasing, for the reasons indicated above. However, it plays a very important role, because of its ability to dissolve fluorides and oxides. In this way, the temperature, conductivity, viscosity, and density of the bath can be affected. This property is especially useful in refining baths, which must have a high density to facilitate separation of the fused aluminum. High density is attained by dissolution of barium fluoride in the cryolite melt.

The other uses for cryolite are practically the same as those of aluminum fluoride. In addition, cryolite is used as a filler for resins and in grinding wheels.

3.7. Economic Aspects

The principal use of aluminum fluoride and cryolite is in electrolytic aluminum production. The forecasts of aluminum production made in 1975 turned out to be far from accurate: for example, production in the USA in 1983 was below 4×10^6 t [123, nos. 7 021 001 G and T], as against a forecast of close to 10×10^6 t. The same is true for Japan: the production dropped from 994×10^3 t in 1981 to 446×10^3 t in 1984.

This unpredicted decrease in aluminum production explains the significant variations in the production and consumption of aluminum fluoride and cryolite recorded in the principal countries between 1975 and 1984 and, above all, the significant differences found between capacity and production. When all aluminum potlines have been equipped with the dry method's process (Section 3.1.2.3), the consumption of aluminum – fluorine compounds will decrease considerably (Tables 10 and 11).

3.8. Toxicology [126]

The low solubility of *aluminum fluoride* in water limits the toxicity; however, the following data have been noted:

Minimum oral lethal dose for guinea pigs: 600 mg/kg
Threshold limit value: 88 mg/m^3
Contact for 24 h of a dose of 500 mg with the eye of an adult rabbit produces erythemas, edemas, etc.
Subcutaneous injection to frogs: LD_{50}Lo: 1 680 mg/kg

The only danger presented otherwise by AlF_3 is caused by its hydrolysis during heating >300 °C in the presence of water vapor: in this case, it is the HF that is toxic.

The low solubility of *cryolite* in water makes it relatively nontoxic; however, on ingestion, the gastric acidity increases this solubility. LD_{50}: 200 mg/kg.

4. Other Metal Fluorides

Ammonium fluorides are included in this chapter because their behavior is very similar to that of the alkali-metal fluorides.

Table 10. Economic data for aluminum fluoride

Country or region	Year	Capacity 10^3 t/a	Production 10^3 t/a	Consumption	Prinicpal companies

4.1. Ammonium Fluorides

Ammonium fluoride [*12125-01-8*] (M_r = 37.04), NH_4F, is a colorless, hygroscopic salt. It crystallizes in the hexagonal system. Its solubility in water is about 1000 g/L at 0 °C. It decomposes on heating to NH_3 and $NH_4F \cdot HF$. The latter, known as ammonium bifluoride [*1341-49-7*] (M_r = 57.04), is a white, transparent, hygroscopic salt (*mp* 126.1 °C, *bp* 239.5 °C) crystallizing in the orthorhombic system. Anhydrous ammonium fluoride is prepared by reacting anhydrous NH_3 and HF or by heating aqueous solutions of NH_4F at reduced pressure, so that a mixture of H_2O and NH_3 is distilled [127]. Very pure metal fluorides (CaF_2, MgF_2, etc.) may be prepared by reaction of NH_4–HF with the metal carbonates [128]. Direct fluorination of $NH_4F \cdot HF$ by elemental fluorine is employed for the manufacture of NF_3 (see Section 6.2).

Aqueous solutions of $NH_4F \cdot HF$ are used instead of hydrofluoric acid in many fields: decoration of glassware, glass washing, decolorization of iron stains on textiles, fungicidal treatment of wood [129], and etching of metals [129]. These surface treatments with $NH_4F \cdot HF$ solutions are used on many metals, for example: formation of a glazed finish on aluminum surfaces [130], removal of thin layers of surface oxides from thin aluminum films in integrated semiconductor circuits [131], and activation of magnesium [132] or steel [133] substrates before nickel plating or phosphatizing [133].

Solutions of $NH_4F \cdot HF$ in anhydrous HF have been proposed as electrolytes, for example, for the industrial production of elemental

fluorine [134], but this process is not yet in use because of corrosion problems (see Fluorine, Chap. 4.4.); however. these electrolytes are suitable in special small-scale electrolysis cells for the fluorination of organic molecules [135] and the deposition of conducting polyaniline coatings on electrodes [136].

4.2. Cobalt Fluorides

Cobalt difluoride [*10026-17-2*] (M_r= 96.93), CoF_2, crystallizes with the rutile structure (*mp* 1200 °C); it is obtained by the action of anhydrous HF on cobalt carbonate, whereas the great oxidizing strength of elemental fluorine or ClF_3 is needed for the preparation of cobalt trifluoride [*10026-18-3*]. CoF_3 (M_r= 115.93) is considered a *solid fluorine carrier* because it can release part of its fluorine in the free form when the temperature is raised:

$$2\,CoF_3 \longrightarrow 2\,CoF_2 + F_2$$

Glemser [137] claims that the decomposition does not really occur below 600 °C. Nevertheless, CoF_3 is a strong fluorinating agent that may be regenerated after use [130]. CoF_3 is especially useful in organic synthesis [138], e.g., for the preparation of perfluorocarbons from the hydrocarbons. Addition of fluorine to halogenated alkenes, such as trichloro trifluoro propene, by reaction with CoF_3 is also possible under carefully controlled conditions [139]. On the other hand, high temperatures and long contact times generally produce highly fluorinated compounds. CoF_3 is also capable of converting most metal oxides to high-oxidation-state metal fluorides.

Special care must be taken during handling, because CoF_3 is toxic and hygroscopic.

4.3. Lithium Fluorides

Lithium fluoride [*7789-24-4*], (M_r= 25.94), LiF, is a white salt (*mp* 846 °C; *bp* 1680 °C) that is sparingly soluble in water. It has the NaCl structure, like all alkali-metal fluorides. It is prepared by the action of hydrofluoric acid on lithium carbonate or hydrogen carbonate. The bifluoride [*12159-92-1*], LiF · HF, is unstable.

Quantities of 1 – 2 % of LiF are added to the electrolyte KF · 2 HF for the production of elemental fluorine. These additions have been reported to be effective for preventing the anode effect by improving the wettability of the carbon electrodes [140], [141]. This is probably related to the property of LiF to form highly conducting ternary compounds $C_xF_yLi_z$ with graphite fluoride [142].

LiF is also used in flux compositions for metal joining and in the ceramics industry. Extremely oxidation-resistant, it is a more efficient lubricant than previously reported soft oxides (PbO) at temperatures above 500 °C [130]. Large, pure crystals of LiF are employed in optical systems for ultraviolet, visible, or infrared light and in X-ray monochromators.

Finally, LiF is a component of many fused electrolytes. For example, the eutectic mixture of LiF, NaF, and KF, known as FLiNaK (composition in mol %: LiF 46.5, NaF 11.5, KF 42.0; *mp* 454 °C) is a suitable electrolyte for the electrodeposition of refractory metals (Zr, Ta, Nb, Cr, Mo, W, and their alloys) as structurally coherent, ductile, fine-grained deposits [143], [144]. This electrolyte is also used in high-temperature batteries.

In nuclear energy production, fused salt breeders, using a mixture of lithium, beryllium, and thorium fluorides at 500 °C, have been proposed as a replacement for the conventional pressurized-water reactors employing uranium. Molten LiF or Li_2BeF_4 have also been considered for fusion reactors in the breeding part or for cooling [145].

The world consumption of LiF is ca. 250 tonnes per year [146].

4.4. Magnesium Fluoride

Magnesium fluoride [*7783-40-6*], (M_r= 62.31), MgF_2, is a colorless salt with the rutile structure. It is formed by reaction of magnesium oxide and HF or magnesium carbonate and NH_4F · HF [128]. It is also a byproduct from the manufacture of elements such as beryllium by reduction of the corresponding fluoride by magnesium metal [147].

In Mg metallurgy and in the ceramics industry, MgF_2 is used as a flux. Single crystals of alkaline-earth fluorides, such as MgF_2, are

suitable for optical applications because of their large domain of transparency from the ultraviolet to the middle infrared region [130]. Infrared transparent windows may be prepared by hot-pressing MgF_2 powder [148].

Ternary intercalation compounds of graphite with fluorine and MgF_2 have been prepared [142]; these compounds have high electrical conductivity and would therefore have an important potential as cathodes or new electroconductive materials. Finally, the eutectic $NaF-MgF_2$ has been proposed in advanced latent-heat energy storage for solar power systems [149].

4.5. Nickel Fluorides

Nickel(II) fluoride [*10028-18-9*], (M_r= 96.71), NiF_2, is a green salt that sublimes above 1000 °C. It crystallizes with the rutile structure and is slightly soluble in water or anhydrous HF and more soluble in aqueous HF.

Nickel(II) fluoride is used in the manufacture of zinc oxide-based ceramic varistors [150] and in organic synthesis as a hydrofluorination catalyst [151]. The addition of NiF_2 to molten $KF \cdot 2\,HF$ has been reported to be effective in preventing the anode effect in fluorine manufacture [140], probably because, during electrolysis, the carbon anode is coated with a catalytic layer containing nickel ions in the higher oxidation state (+4).

Numerous complex salts of nickel(III) or (IV) have been reported in the literature [152], such as M_3NiF_6 and M_2NiF_6, where M = Na, K, Rb, or Cs. They are prepared by the action of a strong fluorinating agent on a mixture of nickel and alkali-metal halides. For example, K_2NiF_6 [*17218-47-2*] may be prepared by the action of elemental fluorine on a mixture of KCl and $NiCl_2$ at 275 °C [153]. These complex salts of Ni(III) and (IV) are fluorinating agents in anhydrous HF, and some of them can be used as sources of pure elemental fluorine [154].

Bis(tetrafluoroammonium) hexafluoronickelate [*63105-40-8*], $(NF_4)_2NiF_6$, which is a solid fluorine carrier, has been proposed as a high-energy solid-propellant oxidizer. It is prepared from Cs_2NiF_6 and NF_4SbF_6 in anhydrous HF [155].

4.6. Potassium Fluorides

Potassium fluoride [*7789-23-3*], (M_r= 58.10), KF, is a colorless to white hygroscopic salt that crystallizes with the NaCl structure (*mp* 858 °C, *bp* 1505 °C). Two hydrates are known: $KF \cdot 2\,H_2O$ (*mp* 41 °C) and $KF \cdot 4\,H_2O$ (*mp* 19 °C).

Potassium fluoride is prepared by reacting potassium carbonate (or KOH) with aqueous hydrofluoric acid. Care is necessary in handling the anhydrous salt, to prevent its hydration.

The anhydrous salt is used in preparing silver soldering fluxes. For brazing, mixtures of alkaline borates and potassium fluoride are generally preferred, but a mixture of KF and AlF_3 has been proposed for brazing aluminum and its alloys [156].

Anhydrous KF is used in organic synthesis as a catalyst for various reactions [157], [158] or to introduce fluorine into organic molecules [146], [159]. For example, fluoro compounds can be prepared by replacing labile chlorine atoms by fluorine atoms, as in the manufacture of sodium fluoroacetate, a rat poison. The nucleophilic strength of F^- and the solubility of KF in aprotic organic solvents may be improved by using crown ethers. The "naked" fluoride ion obtained is an efficient fluorinating agent [159].

Potassium fluoride is a component of an electrolyte known as FLiNaK (see Section 4.3).

In France, potassium fluoride may be added to table salt to increase resistance to dental caries: 0.76 g KF, corresponding to 0.250 g of fluorine, is added per kilogram of NaCl [160].

The tetrahydrate, $KF \cdot 4\,H_2O$, has been proposed for the storage of heat (below 100 °C) because its melting point is close to room temperature [145].

Potassium bifluoride [*7789-29-9*] (M_r= 78.11), $KF \cdot HF$, also called Frémy's salt, is a white, crystalline salt (*mp* 239 °C). It is prepared from potassium carbonate or hydroxide and aqueous hydrofluoric acid. The concentrated solution is cooled to permit crystallization. A process including precipitation in the presence of a saturated alcohol (ethanol, propanol) has been described in the patent literature [161]. $KF \cdot HF$ can also be obtained from fluosilicic acid [162]. Thermal decomposition of $KF \cdot HF$ produces HF.

Potassium bifluoride is used in fluxes [163], [164], in etching metals such as aluminum [129], [165], in frosting glass [166], and in the treatment of wood to prevent fungal attack [129], [167]. $KF \cdot 2\,HF$ [*12178-06-2*] (*mp* 71.7 °C) is prepared from commercial Frémy's salt and HF. In all modern fluorine-production units, the electrolyte has the approximate composition $KF \cdot 2\,HF$ for temperatures ranging from 80–110 °C (see Fluorine, Chap. 4.4.).

4.7. Sodium Fluorides

Sodium fluoride [*7681-49-4*] (M_r = 41.99), NaF, is a white, crystalline salt with the NaCl structure (*mp* 992 °C, *bp* 1704 °C). Its solubility in water is ca. 40–50 g/L between 0 and 100 °C. Relatively high concentrations of fluoride ions have toxic effects; the lethal dose for a 70-kg human is estimated to be 5–10 g of sodium fluoride [168]. NaF is made by reacting sodium carbonate or hydroxide with hydrofluoric acid; separation of the NaF from the solution and drying may be improved by adding a saturated alcohol (ethanol, propanol) to the solution [169]. If excess acid is added, sodium bifluoride [*1333-83-1*] (M_r = 61.99), $NaF \cdot HF$, is formed. At present, $NaF \cdot HF$ and NaF are frequently prepared from inexpensive materials such as the waste gases from superphosphate manufacture by conversion of H_2SiF_6 [170], [171]. The annual consumption of NaF is estimated at several million tonnes [146].

On heating above 160 °C, $NaF \cdot HF$ decomposes to NaF and HF. Use is made of this property in fluorine manufacture: the anodic gases, mainly composed of fluorine, contain ca. 7–10 % HF, which can be partially removed by condensation. If a low level of contamination is required, e.g., <0.02 vol %, HF is absorbed by sodium fluoride, forming $NaF \cdot HF$. The absorbent is regenerated by heating.

Sodium fluoride may be added to drinking water (0.7–1 mg F^-/L) to increase resistance to dental caries. It is also used for pickling stainless steel, in soldering and metallurgical fluxes, and in wood treatment [167].

In the reprocessing of irradiated fuels, ruthenium, niobium, and antimony can be separated by absorbing them on, or complexing them with, NaF at 400 °C [130]. NaF is a component of an electrolyte known as FLiNaK (see Section 4.3).

Sodium bifluoride is a good laundry sour: it removes iron stains and does not attack textile fibers. It is also used in etching and frosting glass [166], and in cleaning stone and brick facades. In aluminum manufacture, cryolite may be prepared by the reaction of aluminum hydroxide, $Al(OH)_3$, with solid $NaF \cdot HF$ [172].

4.8. Tungsten Hexafluoride

Tungsten hexafluoride [*7783-82-6*] (M_r = 297.84), WF_6, is a colorless gas at room temperature (*mp* 2.5 °C, *bp* 17.1 °C), which is hydrolyzed by water to WO_3. Its reactivity as an oxidant has been compared with that of hexafluorides of other transition metals [173], [174]: It is a mild oxidant and a poor fluorinating agent [174]. Its electrochemical behavior in anhydrous hydrogen fluoride was studied [175], and a new general preparative route for lower fluorides and hexafluorometallates of the transition metals ($NaWF_6$, etc.) was reported.

Tungsten hexafluoride is manufactured by the direct action of elemental fluorine on solid powdered tungsten, e.g., in a flame reactor. It is stored in steel containers (1–1000 kg). Its major use is in chemical vapor deposition (CVD), which produces tungsten coatings on both conducting and insulating substrates. Two chemical reactions are used to form such a deposit: (1) reduction of WF_6 by hydrogen at an elevated temperature or (2) thermal decomposition of WF_6. High-purity CVD coatings of tungsten, sometimes alloyed with rhenium, have found application, e.g., as targets for the production of X-rays [176] and solar energy collectors [177].

5. Fluorine–Silicon Compounds

Fluorine–silicon compounds contain two elements, silicon and fluorine, that are abundant in the earth's crust. They are raw materials used in the manufacture of broadly developed industrial products, such as aluminum and its derivatives. They are also used in the fine chemistry of electronic silicon. They provide potential access to anhydrous hydrofluoric acid. Because of the diversity of their reactions, silicon tetrafluoride

and fluosilicic acid and its salts are important intermediates.

5.1. Silicon Tetrafluoride

Under normal temperature and pressure, silicon tetrafluoride or tetrafluorosilane [*7783-61-1*], SiF_4, M_r= 104.09, is a colorless gas with a suffocating odor, which hydrolyzes rapidly in humid air. It can be manufactured by direct synthesis from the elements, but it usually arises as an industrial byproduct of the treatment of fluorine-containing minerals, such as fluorite or fluorapatites. The market for this product is limited. The potential for development lies in the production of finely divided silicas, electronic silicon, and optical fibers.

5.1.1. Physical Properties

The principal physical properties are shown in Table 12 [178], [179]. The sublimation curve is represented by the equation:

$$\log p = -1346.2T^{-1} + 12.61$$

The vaporization curve is represented by:

$$\log p = -975.0T^{-1} + 10.578$$

with p expressed in Pascal [180]. The changes in the other principal physical properties with temperature have been presented in the form of curves [181].

Table 12. Physical properties of silicon tetrafluoride

Property	Value
Boiling point *bp*	−90.2 °C (175.7 kPa) −86.8 °C (223.8 kPa)
Density ϱ	
Gas (STP)	$4.69 \cdot 10^{-3}$ g/cm^3
Liquid at −80 °C	1.598 g/cm^3
Solid at −195 °C	2.145 g/cm^3
Critical constants	
Temperature t_{crit}	−14.15 °C
Pressure P_{crit}	3.713 MPa
Thermodynamic constants	
Standard heat of formation ΔH_f°	−1614.94 kJ/mol
Standard free energy of formation ΔG_f°	−1572.65 kJ/mol
Specific heat C_p	73.64 Jmol^{-1} K^{-1}
Entropy S_{298}°	282.49 Jmol^{-1} K^{-1}

5.1.2. Chemical Properties

Tetrafluorosilane is an extremely stable product: it is not decomposed by an electric spark or by heating to 800 °C. However, its important property is its hydrolysis in the presence of water or water vapor. In the gas phase, hydrofluoric acid and finely divided silica form [182], creating abundant silica smoke,

$$SiF_4 + 2\,H_2O \rightleftharpoons SiO_2 + 4\,HF - 107.8\,kJ$$

In the aqueous phase, the final products are fluo-silicic acid and silica:

$$3\,SiF_4 + 2\,H_2O \longrightarrow 2\,H_2SiF_6 + SiO_2$$

Bases and sodium carbonate in dilute aqueous solution hydrolyze SiF_4 with formation of fluosilicate. e.g.:

$$3\,SiF_4 + 4\,NaOH \longrightarrow 2\,Na_2SiF_6 + SiO_2 + 2\,H_2O$$

Excess alkaline reagent decomposes the fluosilicate to fluoride:

$$Na_2SiF_6 + 4\,NaOH \longrightarrow 6\,NaF + SiO_2 + 2\,H_2O$$

Gaseous ammonia forms the solid adduct $SiF_4 \cdot NH_3$. Amines react similarly [183].

Metal oxides react with SiF_4 to form silica and the corresponding fluoride or fluosilicate. Metal chlorides lead to exchange reactions between Cl and F, with the formation of chloride fluorides [184].

Organic compounds form addition compounds. This is the case with alcohols [185] and especially with organomagnesium compounds (Grignard reagents), which lead to alkyl or aryl silicyl fluoride derivates [186].

5.1.3. Manufacture

Processes. The oldest manufacture of tetrafluorosilane was carried out by the action of sulfuric acid on fluorite. The presence of silica in the ore leads to the formation of SiF_4:

$$2\,CaF_2 + 2\,H_2SO_4 + SiO_2 \longrightarrow SiF_4 + 2\,CaSO_4 + 2\,H_2O$$

However, the most widely used processes start with either silica and hydrofluoric acid or fluosilicic acid or its salts.

Hydrofluoric acid is injected in gaseous form at the bottom of a quartz-lined vertical reactor. Improvements consist of injection of either gaseous or liquid hydrofluoric acid into different stages of the reactor for better control of the reaction temperature [187].

The silica may be dispersed in concentrated sulfuric acid, into which the gaseous hydrofluoric acid is injected [188]. A more advantageous continuous process uses fluosilicic acid instead of hydrofluoric acid, introduced with silica into a column whose upper part is fed with concentrated sulfuric acid [189].

Sodium fluosilicate can be treated with concentrated sulfuric acid, with stirring, in the presence of silica:

$$2\,Na_2SiF_6 + 2\,H_2SO_4 + SiO_2 \longrightarrow 3\,SiF_4(g) + 2\,Na_2SO_4 + 2\,H_2O$$

Sodium fluosilicate can also be heated to cleave the molecule:

$$Na_2SiF_6 \longrightarrow 2\,NaF + SiF_4$$

Heating the product to around 900 °C produces silicon tetrafluoride at pressures of 0.06 MPa [190]. Other fluosilicates, e.g., the barium salt can be used. These processes lead to a very pure product.

All of these processes lead to gaseous SiF_4, which is dried, generally in a column of concentrated sulfuric acid, and then compressed and stored in pressure-resistant steel containers at 6.9 MPa.

Materials. In the manufacture of silicon tetrafluoride, hydrofluoric acid is present either as a raw material or in a stage of the process. This requires material and technology related to those used in the manufacture of hydrofluoric acid. However, pure anhydrous gaseous SiF_4 is only very slightly corrosive.

Environmental Protection. The product is a gas that, upon contact with atmospheric moisture, hydrolyzes to form hydrofluoric acid. Ventilation should be provided in the work areas, in case of the accidental emission of gases. The effluents are to be treated with an alkaline solution to trap the acid and with a calcium salt, which precipitates F^- ions. The waste standards depend on the legislation of each country.

5.1.4. Transport

Silicon tetrafluoride, a toxic gas with a secondary corrosive danger, is subject to national and international transport regulations. The product is listed in the UNO international nomenclature under number 1859.

5.1.5. Analysis

A chromatographic method is used for gases. After dissolution in aqueous medium, analytical methods for fluosilicic acid can be applied (see 5.2.5).

5.1.6. Use

The industrial use of silicon tetrafluoride is limited. The treatment with SiF_4 of concretes and cement parts that must withstand corrosion has been developed during the last twenty-five years [191]. The hydrolysis of silicon tetrafluoride in a high-temperature flame is a process for the manufacture of finely divided pyrogenic silica with a large specific surface area [192]. Silicon tetrafluoride has been used in the manufacture of silane [*7803-62-5*] and of photovoltaic or electronic silicon, e.g., in the processes of Allied Chemical Company [193] and Sharp Corporation [194].

Byproduct silicon tetrafluoride is converted in the phosphoric and hydrofluoric acid plants to fluosilicic acid, which can be transported and used as a raw material.

Union Carbide (Matheson Department) is one of the oldest producers. New facilities producing under 100 t/a have been announced by Allied Chemical Company (USA) and Central Glass (Japan). Sales are small, e.g., $ 1 000 000 in the USA in 1983 [195].

5.1.7. Toxicology [196]

Silicon tetrafluoride is a nonflammable gas that is highly irritating to the skin and eyes. When

heated, it decomposes and emits toxic fluorine compounds. Threshold limit value (time-weighted average): 2.5 mg (F)/m^3.

5.2. Fluosilicic Acid

Fluosilicic acid or hydrofluosilicic acid [*16961-83-4*], H_2SiF_6, M_r = 144.09, is used mainly in the form of aqueous solutions obtained by the treatment of fluorapatites. It is a raw material for the manufacture of aluminum fluoride and synthetic cryolite. The foreseeable development lies as a raw material to replace fluorite in the manufacture of anhydrous hydrofluoric acid, when the material problems have been resolved.

5.2.1. Physical Properties

Fluosilicic acid does not exist in the anhydrous state but only in aqueous solutions, whose properties depend on the concentration of H_2SiF_6 and the temperature. At 17.5 °C the density of fluosilicic acid solutions has the following values:

% H_2SiF_6	5	10	15	20	25	30
d, g/cm^3	1.0407	1.0834	1.1281	1.1748	1.2235	1.2742

At 25 °C, a 60.79 % solution has a specific gravity of 1.4634 [197], [198].

The freezing point depression in water is 0.317 °C for 1 wt % fluosilicic acid. Mono-, di-, and tetrahydrates are present in the solid state.

Distillation of a fluosilicic acid solution produces a gas phase consisting of silicon tetrafluoride, hydrofluoric acid, and steam. A mole ratio HF: SiF_4 of 2 in the gas phase, corresponding to fluosilicic acid, is the case only over an aqueous phase containing 13.3 wt % of fluosilicic acid. For lower concentrations, the mole ratio HF : SiF_4 is greater than 2 in the gas phase, i.e., the aqueous phase is enriched in silica. For solutions of 13.6 wt % or higher, the molar ratio HF : SiF_4 decreases, becoming less than 1 for 30 wt % fluosilicic acid. Hydrofluoric acid is enriched in the aqueous phase, and silicon tetrafluoride is enriched in the gas phase [199].

In contrast, another study found the partial pressures of SiF_4 and HF in the vapor phase to fit the following equations [200]:

$$\log p_{HF} = (1808.5 - 109.89c)/T - 8.625 + 0.49c$$
$$\log p_{SiF_4} = (1472.89 + 50.02c)/T - 1.625 + 0.386c$$

where p is the partial pressure in Pascal, T the absolute temperature, and c the concentration in wt % of H_2SiF_6 in the aqueous solution.

The presence of a pseudoazeotrope in concentrated solutions is due to the molecular association $H_2SiF_6 \cdot SiF_4$ and to a desolvation of SiF_4 [201]. Distillation and concentration of fluosilicic acid, without precipitation of silica, is possible if hydrofluoric acid is present. For example, a solution containing 36 % of fluosilicic acid and 10 % of hydrofluoric acid, boiling at 116.1 °C at 101.26 kPa, can be obtained [202].

The most recent thermodynamic values [203], [204] are:

$\Delta H_f^0 = -2376.5$ kJ/mol
for H_2SiF_6 in a solution containing 41 moles of HF and 75 moles of H_2O
$\Delta H_f^0 = 211.4$ kJ/mol
for $2\,HF(g) + SiF_4(g) \longrightarrow H_2SiF_6(g)$

For the SiF_6^{2-} ion:

$\Delta H_f^0 = -2389.1$ kJ/mol
$\Delta G_f^0 = -2199.4$ kJ/mol
$S_{298} = 122.2$ J mol^{-1}K^{-1}

5.2.2. Chemical Properties

Fluosilicic acid is a strong acid in aqueous solution. The neutralization and the decomposition of the acid can be distinguished in the overall neutralization curve. Two equilibria occur in aqueous solutions:

$$SiF_6^{2} \rightleftharpoons SiF_4 + 2\,F^-$$
$K = 1 \cdot 10^{-6}$ [205]
$$SiF_6^{2} + 2\,H_2O \rightleftharpoons SiO_2 + 4\,H^+ + 6\,F^-$$
$K = 1.2 \cdot 10^{-27}$ [206]

The careful addition of strong bases under vigorous agitation leads to the formation of the fluosilicate. Sodium or ammonium fluosilicate can be produced by this reaction. On the other hand, any excess of reagent over the stoichiometric quantity gives silica and the fluoride, as

a result of a displacement of the second equilibrium. Sodium or ammonium fluoride can be manufactured by this method. In the case of the aluminum salt, the silica precipitates but the aluminum fluoride supersaturates.

In highly acid medium, particularly in concentrated sulfuric acid, the fluosilicic acid is cleaved according to the first equilibrium to give silicon tetrafluoride, which is insoluble in the medium, and hydrofluoric acid, which stays in solution.

Fluosilicic acid displaces the Cl^- ion of sodium chloride with formation of hydrochloric acid and sodium fluosilicate:

$$H_2SiF_6 + 2\,NaCl \longrightarrow Na_2SiF_6 + 2\,HCl$$

5.2.3. Manufacture

Raw Materials. Fluosilicic acid can be manufactured from silica and aqueous hydrofluoric acid solutions, but in practice only silicon tetrafluoride, a byproduct from other processes, is used.

Fluosilicic acid solutions are produced in hydrofluoric acid plants as a result of the presence of silica in the fluorite ore. Approximately 50 kg of H_2SiF_6 is produced per tonne of HF. This represents an annual potential of 50×10^3 t of fluosilicic acid on a worldwide basis (see Section 1.3.2).

Fluosilicic acid is produced during the manufacture of fertilizers or of wet-process phosphoric acid by the action of sulfuric acid on fluorapatite ores. Silicon tetrafluoride and hydrofluoric acid are emitted during the reactions and, above all, during the concentration of phosphoric acid from 30 wt % to 40 and 52 wt % P_2O_5.

Processes. The reaction of a dilute solution of hydrofluoric acid and fluosilicic acid on silica takes place in equipment permitting good contact of the reagents. A vertical column containing powdered silica and fed with liquid at approximately 50 °C is suitable [208] and produces a concentrated fluosilicic acid solution (42 – 43 wt % H_2SiF_6) containing only traces of hydrofluoric acid.

The processes for fluosilicic acid manufacture are normally integrated in the plants for manufacture of superphosphate or phosphoric acid. They consist of a recovery of the gases rich in silicon tetrafluoride and hydrofluoric acid. These gases also contain water vapor and droplets of phosphoric acid.

The recovery is carried out in several columns placed in series and fed by a fluosilicic acid solution whose content is established by the desired recovery yield, a function of the liquid : gas ratio at operating temperature. The solution obtained contains 15 – 25 wt % of H_2SiF_6, [209–212].

The effectiveness of the processes lies in limiting the entrainment of phosphoric acid. Several systems exist; the following are typical:

1) Mechanical devices, such as cyclones, and baffles operating dry or with aqueous medium and recycling of the liquid [213].
2) Packed or sprayed columns providing intimate contact between the gases and the sprayed liquid that consists of a fluosilicic acid solution, which is recycled to the phosphoric acid concentrators [214].

A very effective process consists of using as the wash liquid sulfuric acid containing 80 % H_2SO_4 which, when saturated with hydrofluoric acid, lets the SiF_4–HF mixture pass, while ensuring the retention of phosphoric acid droplets. The contaminated sulfuric acid is recycled to the phosphate ore treatment unit. This process can be applied to the gases discharged from the manufacture and concentration of phosphoric acid or from superphosphate fertilizer units [215].

The use of one of these two types of purifiers, or of a combination of the two, considerably reduces the phosphorus content of the fluosilicic acid recovered downstream.

The phosphate content, expressed as a mass ratio P_2O_5 : F, of close to 0.03 – 0.05 in the entering gases is reduced to 0.002 – 0.005 with a mechanical system. With a wash column, the ratio drops to 0.001. With the two systems placed in series and a low gas velocity, a ratio of 0.0007 can be reached [216]. This reduced phosphate content is important when the acid is to be used in the manufacture of aluminum fluoride or cryolite.

Materials. The construction materials for the columns and storage units must be resistant to an aqueous medium of fluosilicic acid and dilute hydrofluoric acid. Ebonite-coated steels are suitable. Plastics, such as polyethylene and polypropylene, show good resistance. The use of metals should be preceded by corrosion tests.

5.2.4. Transport

Fluosilicic acid, a dangerous and corrosive material, is subject to national and international regulations relating to transport by railroad (RID), road (ADR), and to international maritime transport regulations. The quantities that can be transported by air are limited. The product is listed in the UNO international nomenclature under number 1778.

5.2.5. Quality and Analysis

Fluosilicic acid is marketed in the form of aqueous solutions containing 20 – 35 wt % H_2SiF_6. It generally contains an excess of fluorine over the stoichiometric quantity of the formula. The commercial product may also contain chloride, phosphate, sulfate, and traces of sulfur dioxide and metallic impurities.

The number of standard analytical methods is small: potentiometric determination of fluorine, ISO 6677 (1983), and some standard analyses for sodium fluosilicate, other analyses have been proposed. Classical methods, such as acidimetry in alcoholic medium [217–219] and determination of $HF - H_2SiF_6$ acid mixtures [220], can be used. Impurities are determined by conventional methods after evaporation in the presence of sodium carbonate.

5.2.6. Use

The first use of fluosilicic acid was as a bactericidal and fungicidal agent (breweries, wood). Like silicon tetrafluoride, fluosilicic acid changes the setting rate and the texture of cement [191].

The aluminum industry is the largest consumer of fluosilicic acid (40 % in the USA), where it is used for the manufacture of aluminum fluoride and cryolite [221].

The manufacture of sodium, ammonium, magnesium, and potassium fluosilicates is also important (30 % of the demand in the USA). Finally, the use fluosilicic acid in water fluoridation, in competition with alkali metal fluorides, is developing in the USA.

Fluosilicic acid is also a raw material for the manufacture of hydrofluoric acid, but corrosion problems are limiting the development of this type of process.

5.2.7. Economic Aspects [222]

The USA is the country producing the largest amount of fluosilicic acid, approximately 90 000 t/a in terms of 100 % H_2SiF_6 by more than 25 companies operating phosphoric acid and superphosphate plants. Only three companies carry out production not combined with phosphate production.

In other countries, fluosilicic acid is used principally in the manufacture of aluminum fluoride. There are few commercial transactions, because the product is frequently used on site. The listed selling price was of the order of $ 100/t of 100 % material in 1982 [223].

5.2.8. Toxicity [224]

Fluosilicic acid irritates mucous membrane, eyes, and skin and emits corrosive and toxic fluoride vapors. The lowest published subcutaneous lethal dose for the frog is 140 mg/kg, while the threshold limit value (time-weighted average) is 2.5 mg (F)/m^3.

5.3. Fluosilicates

Fluosilicates are the salts produced by reaction of fluosilicic acid with bases or metal salts. The most important fluosilicate is sodium fluosilicate. Other fluosilicates, such as those of ammonium, potassium, zinc, and magnesium, have also been produced commercially.

Table 13. Solubilities of some fluosilicates in water in g/100 g of water

Fluosilicate	Temperature 20 °C	25 °C	50 °C	100 °C
$BaSiF_6$ [*17125-80-3*]		0.025		0.044
K_2SiF_6 [*16871-90-2*]		0.177		0.82
$MgSiF_6$ [*16949-65-8*]	23.00		28.54	
Na_2SiF_6 [*16893-85-9*]	0.64	0.76	1.27	2.45
$(NH_4)_2SiF_6$ [*16919-19-0*]		18.5	26.15	37.90
$ZnSiF_6$ [*16871-71-9*]	35.16		38.30	42.18

5.3.1. Properties

The solubilities of some fluosilicates in water as functions of temperature [225] are shown in Table 13. Solutions of fluosilicates are sensitive to hydrolysis in alkaline medium [226]:

$$SiF_6^{2-} + 4\,OH^- \rightleftharpoons SiO_2 + 2\,H_2O + 6\,F^-$$

Dispersions of fluosilicates by peptization of solutions are obtained by adding a salt, a polyhydric alcohol, and a weak base to the solution [227]. In the presence of acid, fluosilicate solutions release silicon tetrafluoride.

The thermal decomposition of fluosilicates takes place with release of gaseous silicon tetrafluoride and formation of the solid fluoride [228]. This decomposition, particularly in the case of the barium salt, provides SiF_4 for use in electronics [229].

5.3.2. Manufacture

The manufacture of fluosilicates, especially the sodium salt, is carried out by neutralization of fluosilicic acid. The operation is carried out under vigorous agitation, with control of the ratio of reagents in order not to simultaneously produce the fluoride by introduction of excess alkali. Sodium fluosilicate precipitates in good yield because of its low solubility. It can be purified by dissolution in aqueous sodium chloride [230]. For the more soluble ammonium fluosilicate, vacuum crystallization is necessary to increase the yield, or crystallization must be carried out at low temperature [231]. The precipitates are washed and dried.

Sodium and potassium fluosilicates are also prepared by the action of fluosilicic acid on the alkali-metal chloride. The products are filterable solids [232], [233].

Zinc, magnesium, and barium fluosilicates are obtained by the action of fluosilicic acid on a salt of the corresponding metal, such as the carbonate.

5.3.3. Analysis

There are some standard analytical methods for sodium fluosilicate:

ISO TC 47/4281 for free acidity
ISO TC 47/5442 for sulfur
ISO TC 47/54443 for iron
ISO TC 47/5915 for granulometry
ISO TC 47/6229 for free silica

5.3.4. Uses, Economic Aspects

Sodium fluosilicate, the most important fluosilicate, is used in water treatment in some countries, especially in the USA, in the treatment of effluents of industrial laundries [234], and in glass manufacture as a polishing or etching additive [235]. It is also a raw material for cryolite and for silicon tetrafluoride.

The less important ammonium fluosilicate is also used in industrial laundries. The other fluosilicates have different uses: the magnesium salt acts as a hardener for concrete, and the potassium salt is used in the manufacture of porcelain enamels and porcelains [236]. The building industry uses fluosilicates in coatings for the protection of walls and floors against certain chemical agents [237–239]. The barium salt is a luminophor in ultraviolet lamps [240].

The fungicidal and insecticidal properties of fluosilicates have been used in certain commercial products [241].

The price of sodium fluosilicate was $ 270 per tonne in 1982 [242].

5.3.5. Toxicity

For sodium fluosilicate [243]:

oral LD_{50} for the rat	125 mg/kg
published minimum	70 mg/kg
subcutaneous lethal dose for the rat	
published minimum oral lethal dose for the rabbit	125 mg/kg
published minimum	448 mg/kg
subcutaneous lethal dose for the frog	2.5 mg (F)/m^3
threshold limit value (time-weighted average)	

Other slightly soluble or soluble fluosilicates, where the cation is not toxic, have similar toxicities.

6. Other Inorganic Fluorine Compounds

6.1. Sulfur Fluorides [244], [245]

Among the sulfur–fluorine compounds S_2F_2, SF_2 [*13814-25-0*] and its dimer S_2F_4 [*27245-05-2*], SF_4 [*7783-60-0*], S_2F_{10} [*5714-22-7*], and SF_6 [*2551-62-4*], only two have important industrial applications: SF_4 and SF_6.

Physical properties of S_2F_2 have been reported since 1923 [246]. Two isomeric forms have been established [247]: pyramidal molecules of thiothionyl fluoride $S=SF_2$ [*16860-99-4*] and nonplanar chains F–S–S–F of difluorodisulfane [*13709-35-8*].

Sulfur difluoride, SF_2, and its dimer S_2F_4 are not especially stable. A review of the properties of these lower sulfur fluorides, including difluoropolysulfanes S_nF_2, has been published [248].

Disulfur decafluoride, S_2F_{10} (M_r = 254.11), is extremely toxic, causing the death of rats within 16–18 h of exposure to S_2F_{10} vapors at a concentration of 1 ppm. It is a colorless, volatile liquid (*mp* – 92 °C, *bp* 29 °C) that does not react with water at ambient temperature. The molecule is composed of two octahedral SF_5 groups linked by an S–S bond. It decomposes at ca. 200 °C:

$$S_2F_{10} \longrightarrow SF_4 + SF_6$$

a reaction used in the purification of SF_6.

The preparation, physical, and chemical properties of thionyl fluoride [*7783-42-8*], SOF_2 [249], and sulfuryl fluoride [*2699-79-8*], SO_2F_2, [250] have been reviewed. The latter has special industrial applications: fumigation of food material [251] and catalysis.

6.1.1. Sulfur Hexafluoride [252]

Preparation. Elemental fluorine is not necessary for the preparation of SF_6, which can be made by pyrolyzing SF_5Cl, the latter manufactured by the reaction of sulfur or a sulfur chloride with chlorine and an amine –HF complex [253]. The electrochemical production of SF_6 has been patented [254], [255].

However, almost all methods consist of burning sulfur in a stream of fluorine:

$$S + 3F_2 \longrightarrow SF_6 \quad \Delta H = -1096\,\text{kJ/mol}$$

Several techniques are described in the literature [256–259] that use simple sulfur melting pot or flame reactors. The heat of reaction must be removed by cooling the reactor jacket.

The crude gas produced, consisting mainly of SF_6, must be purified because it contains SOF_2, SO_2F_2, and toxic lower fluorides such as S_2F_2, SF_4, and S_2F_{10}. The gases are first washed in a KOH spray scrubber to remove the major portion of the hydrolyzable compounds (S_2F_2, SF_4, HF, F_2, SO_2F_2, etc.). The gas mixture is then passed through a metal tube at 400 °C to pyrolyze the S_2F_{10} to SF_4 and SF_6. Another washing with an alkaline solution is necessary to remove the last portions of hydrolyzable compounds. The gases next pass through a tower containing a suitable drying material, such as alumina, phosphorus pentoxide, or barium oxide, before being purified over charcoal, distilled, compressed, and transferred to steel cylinders for storage.

Properties. Discovered in 1900 [260], sulfur hexafluoride (M_r = 146.05) is a colorless, tasteless, incombustible gas (sublimation point −63.9 °C). Practically inert from a chemical and biological standpoint, it does not react with water, caustic potash, or strong acids and can be heated above 500 °C without decomposition. However, at very high temperatures, or in the presence of an electric arc, SF_6 slowly decomposes, yielding toxic byproducts including lower

fluorides of sulfur. The chemical inertness of SF_6 is due to the fluorine shielding of the sulfur atom: the molecule is octahedral, S being covalently saturated by six fluorine atoms. SF_6 has a high dielectric strength and a high recombination rate after dissociation by electric discharges. Its dielectric constant has a value of 1.002049. Finally, it is a good acoustic and thermal insulating agent.

These properties are responsible for the specific uses of the gas.

Uses. Because of the good dielectric properties of SF_6 and its ability to trap electrons during arc blowing, 90 – 95 % of the SF_6 produced is used in electromechanical equipment such as high-voltage circuit breakers, compact switching stations that are very safe and need little maintenance, and insulation of electric cables for transmission of high electric power through difficult or protected sites (the importance of this will increase if its cost can be reduced).

Minor uses of SF_6 (about 5 % of the production): insulation of nuclear particle accelerators and X-ray equipment, microwave and radar equipment, thermoacoustic insulation of windows (double-pane systems enclosing SF_6 and offering a high degree of acoustic and thermal insulation [261]), meteorology and medical uses related to its inertness, treatment with a plasma containing SF_6 for etching silicon [262] or for increasing the water repellency and wet strength of kraft paper [263], and protection of molten magnesium in the magnesium industry [264].

Specifications. The byproducts from the production of SF_6 must be completely removed from the product, since they are toxic. The absence of toxic impurities in SF_6 is verified by exposing five albino mice for 24 h to an atmosphere containing 79 % by volume of SF_6 and 21 % O_2. After 72 h, they must show no signs of intoxication [265].

The other specifications [266] are:

air	<500 ppm by weight
CF_4	<500 ppm
H_2O	<15 ppm
acidity, computed as HF	<0.3 ppm
hydrolyzable fluorides, computed as HF	<1 ppm
mineral oil content	<10 ppm

Economic Aspects. SF_6 is shipped as a liquefied gas in steel cylinders (several kg) or in large containers (several hundred kg). Bulk quantities are available in tube trailers.

In 1986, the world market was estimated to be 5000 – 7700 t/a. SF_6 is manufactured by Allied Chemical Corporation and Air Products and Chemicals in the United States; Asahi Glass, Hashimoto Chemical Industries, and Kanto Denka Kogyo in Japan; and Montedison, Kali-Chemie, and ATOCHEM-COMURHEX in Europe. Its price is ca. \$ 4 – 8 per kg and \$ 8 – 12 per kg in 1992 [339].

6.1.2. Sulfur Tetrafluoride [267]

SF_4 (M_r = 108.06) is a colorless, nonflammable gas (mp – 121 °C, bp – 40.4 °C) with a penetrating odor; it is very toxic. The pure gas was first prepared in 1955 by the reaction of fluorine and sulfur at low temperature [268], a technique still used for its manufacture [269]. SF_4 is also produced by reaction of SCl_2 with AM · nHF, where AM is an amine (aliphatic tertiary amine, pyridine, quinoline, etc.) and n = 1 – 4 [270], [271]. Other reactions have been proposed in the patent literature: reaction of SCl_4 or a mixture of SCl_2 and Cl_2 with HF in the presence of CCl_4 [272] or oxidation of sulfur with UF_6 [273].

The SF_4 molecule is a distorted trigonal bipyramid. It reacts rapidly with water:

$$SF_4 + H_2O \longrightarrow SOF_2 + 2\,HF$$

As a consequence, all reactions with SF_4 must be performed under anhydrous conditions.

The high reactivity of SF_4 is used to form selectively fluorinated compounds [274]: $-CF_2-$ groups from ketones or thiocarbonyl compounds; $-CF_3$ groups from carboxylic acids, esters, anhydrides, or amides; and inorganic fluorides MF_x from oxides or sulfides. However, several less important uses have been developed: increasing the water repellency of polymeric materials by treatment with SF_4, preparation of high-lubricity elastomers, and treatment of carbon blacks to prepare improved rubber vulcanizates.

In spite of its interesting properties, the applications of SF_4 are limited because of its *toxicity.* A concentration of 50 ppm was found to

be lethal to one of two animals exposed for four hours; all animals exposed to a concentration of 10 ppm for one hour showed irregular breathing and signs of irritation [275].

SF_4 is supplied as a liquefied gas in steel cylinders (Air Products and Chemicals). The US production is several hundred kilograms per year. The price was about $ 170 per kg in 1982.

6.2. Nitrogen Fluorides [276]

Nitrogen Trifluoride . Among the numerous N – F compounds, only NF_3 [*7783-54-2*] has achieved commercial importance: NF_3 (M_r = 71.00) is a colorless toxic gas (*mp* – 206.8 °C, *bp* – 129 °C). It does not react with common metals, water, or dilute basic or acid solutions at ordinary temperatures, although it is a strong oxidizing agent at elevated temperatures. It fluorinates organic compounds, but the reaction is frequently explosive. It reacts with many metals to produce N_2F_4 and the metal fluoride.

Nitrogen trifluoride is manufactured by direct fluorination of NH_3 or $NH_4 \cdot HF$ by F_2 [277], [278] or by electrolysis of ammonium fluoride-hydrogen fluoride melts [279], [280].

Nitrogen trifluoride is preferred to F_2 in high-power chemical lasers because of its ease of handling at ambient temperatures. Its production is expected to increase in the near future with the development of these lasers. Minor uses have been mentioned in the literature: plasma etching of semiconductor materials [281], production of perfluoroammonium salts, a proposed gas filler to increase the life and brightness of lamps [282], and as an oxidizing agent in rocketry (not yet commercialized).

Other Nitrogen – Fluorine Compounds. Ammonium fluoride is discussed in Chapter 4.

Perfluoroammonium salts, such as NF_4SbF_6 [*16871-76-4*] or NF_4AsF_6 [*16871-75-3*], have been synthesized by reaction of NF_3(g), F_2(g), and SbF_5(l) or AsF_5(l) at 100 – 200 °C under a pressure of $5 - 20 \times 10^6$ Pa (50 – 200 atm) [283]. They are convenient solid sources of F_2 and NF_3 because they are stable up to 200 °C but decompose rapidly above 300 °C, releasing NF_3 and F_2. The thermochemistry of these salts has been studied by Bougon et al. [284].

The properties of the nitrogen – fluorine compounds without commercial importance at the present time have been reviewed in the literature [276]: tetrafluorohydrazine [*10036-47-2*], N_2F_4, difluorodiazine [*10578-16-2*], N_2F_2, and fluorine azide [*14986-60-8*], N_3F. Among oxygenated N – F compounds: nitryl fluoride [*10022-50-1*], NO_2F, nitrogen fluoride oxide (nitrosyl fluoride) [*11094-71-6*], NOF, and fluorine nitrate [*7789-26-6*], NO_3F.

6.3. Oxygen – Fluorine Compounds

All oxygen fluorides have strong oxidizing power. Oxygen difluoride is the most stable.

Oxygen Difluoride [285], [286]. Oxygen difluoride [*7783-41-7*] (M_r = 54.00) is a toxic, colorless gas (*mp* – 223.8 °C, *bp* – 145.3 °C), discovered by Lebeau and Damiens in 1927. The molecule is nonlinear. It may be prepared by several methods: electrolysis of molten KHF_2 in the presence of water [287], electrolysis of aqueous hydrofluoric acid [288], or fluorination of 0.5 M aqueous NaOH [289].

$$2\,F_2 + 2\,NaOH \longrightarrow OF_2 + 2\,NaF + H_2O$$

Pure, dry OF_2 is stable up to 250 °C, but in the presence of water its handling becomes dangerous: mixtures of OF_2 and steam can explode easily because of the reaction

$$OF_2 + H_2O \longrightarrow 2\,HF + O_2$$

Oxygen difluoride reacts like elemental fluorine as a powerful oxidizing agent, but higher activation energies are required to initiate its reactions. Perhaps suitable for rocket and missile propellants, no reactions of particular interest in industrial preparative chemistry have been found, and it remains mainly a laboratory chemical.

Other Oxygen Fluorides [285], [286]. Dioxygen difluoride [*7783-44-0*], O_2F_2, is formed by an electric discharge through a gaseous $O_2 - F_2$ mixture at low pressure and liquid-air temperature. This unstable compound decomposes rapidly to O_2 and F_2 above –78 °C; it reacts explosively with most oxidizable materials, even at cryogenic temperatures.

Trioxygen difluoride, O_3F_2, and tetraoxygen difluoride, O_4F_2, are extremely unstable compounds, even at temperatures as low as −180 °C. They are two of the most powerful oxidants known.

Other Compounds. Hypofluorous acid [*14034-79-8*], HOF, formed by passing F_2 over cold water, has been suggested to be the active intermediate in the F_2–H_2O reaction. Compounds containing the –OF group have been classified as fluoroxides or oxyfluorides, but for inorganic compounds the term hypofluorites appears to be more suitable. The properties of these compounds have been reviewed in the literature [290].

6.4. Phosphorus – Fluorine Compounds [291]

Phosphorus fluorides, phosphorus oxyfluoride, the three fluorophosphoric acids, and their salts, are the most important phosphorus – fluorine compounds.

Phosphorus Fluorides [292], [293]. The most widely studied phosphorus fluorides are PF_3 [*7783-55-3*] and PF_5 [*7647-19-0*]. *Phosphorus trifluoride* (M_r = 87.97) is a colorless gas, slowly hydrolyzed by moist air (*mp* – 151.5 °C, *bp* – 101.8 °C). The molecule has a pyramidal structure and forms many adducts [e.g., $Ni(PF_3)_4$, $PtCl_2(PF_3)_2$] by donating the electron pair on the P atom. Its toxicity is related to its ability, like CO, to form a stable complex with hemoglobin.

A mixture of PF_3 with oxygen can detonate violently, but activation is necessary (electric spark).

$$PF_3 + 1/2\,O_2 \longrightarrow POF_3$$

Both F_2 and Cl_2 react rapidly, with PF_3 leading to PF_5 and PF_3Cl_2, respectively. PF_3 is usually prepared by an exchange reaction between PCl_3 and AsF_3 or SbF_3 in the presence of SbF_5 as the catalyst [294].

Phosphorus pentafluoride (or pentafluorophosphorane), PF_5 (M_r = 125.97), has been widely studied. It is a colorless, strongly fuming gas (*mp* – 93.8 °C, *bp* – 84.6 °C) that is very hygroscopic and easily hydrolyzable: a slight trace of moisture forms POF_3 and HF, and with more water, hydrolysis yields phosphoric acid, with oxyfluorophosphates as intermediates.

The molecule has a trigonal bipyramidal structure corresponding to sp^3d hybridization; PF_5 behaves as a typical electron-accepting Lewis acid. For this reason, it is an excellent Friedel-Crafts polymerization catalyst [295]. Adducts are formed with amines, ethers, and nitriles.

Exchange reactions may be used to prepare PF_5 [292], for example:

$$3\,PCl_5 + 5\,AsF_3 \longrightarrow 3\,PF_5 + 5\,AsCl_3$$

Other fluorinating agents, such as SbF_3 and SbF_5, are more convenient. PF_5 may also be obtained from PF_3, or from the thermal decomposition of sodium hexafluorophosphate between 300 and 1000 °C.

Phosphorus Oxyfluoride. Phosphorus oxyfluoride (phosphoryl fluoride) [*13478-20-1*] (M_r = 103.97), POF_3, is a gas at room temperature. It is formed from PF_5 by reaction with water; further hydrolysis forms a mixture of fluorophosphoric acids. Halide exchange methods allow preparation of POF_3 from $POCl_3$.

The tetrahedral structure of POF_3 is more stable than the 5-coordinate structures; POF_3 is considerably less active than PF_5 toward electron donors.

Fluorophosphoric Acids [296]. *Monofluorophosphoric acid* [*13537-32-1*] (M_r = 99.99), H_2PO_3F, is used as a polymerization catalyst; hydrolysis is complete in dilute solutions:

$$H_2PO_3F + H_2O \longrightarrow H_3PO_4 + HF$$

The most suitable method for the preparation of H_2PO_3F consists of the reaction of phosphorus pentoxide with concentrated hydrofluoric acid:

$$P_2O_5 + 2\,HF + H_2O \longrightarrow 2\,H_2PO_3F$$

Sodium monofluorophosphate is used in toothpastes; it probably facilitates the formation of fluoroapatite in teeth, which increases

resistance to dental caries. Passivation of metallic surfaces by K_2PO_3F (potassium monofluorophosphate) is another field of interest [297]: these coatings provide a good combination of corrosion protection and paint adherence and are superior to Cr(VI) compounds.

The esters of monofluorophosphoric acid are highly toxic nerve gases as a result of their cholinesterase inhibiting power. For example, Sarin [*107-44-8*] has an oral LD_{50} in rats of 550 µg/kg. These compounds are hydrolyzed in alkaline solutions.

Difluorophosphoric acid [*13779-41-4*], HPO_2F_2 (M_r = 101.98), is used as a catalyst. Its potassium salt has been reported to be a stabilizing agent in chloroethylene polymers [298].

Hexafluorophosphoric acid [*16940-81-1*], HPF_6 (M_r = 145.97), was first observed in the product obtained by reacting P_2O_5 with 40 % aqueous HF. The PF_6^- anion is stable and is isoelectronic with SF_6; however, heating with mineral acids results in hydrolysis. Dry alkali-metal salts heated to high temperatures decompose according to the equilibrium:

$$KPF_6 \rightleftarrows KF + PF_5$$

The lithium and potassium salts have been used as electrolytes in lithium anode batteries.

6.5. Halogen Fluorides [299–302]

Fluorine reacts exothermally with the other halogens over a wide temperature range. High oxidation states may be obtained: Br(V) and I(VII). Four compounds have commercial importance: ClF_3, BrF_3, BrF_5, and IF_5.

Physical Properties and Toxicology. Table 14 summarizes the physical properties of the well-known halogen fluorides. The structures of halogen fluorides and oxyfluorides have been reviewed [303]: ClF_3 and BrF_3 (vapor) both have a T-shaped structure, while the structure of BrF_5 and IF_5 is that of a tetragonal pyramid.

At room temperature, ClF_3 is a gas, while BrF_3, BrF_5, and IF_5 are liquids. All of these compounds are toxic; ClF_3 is considered to be the most toxic (of the order of HF) and most hazardous. It is extremely irritating to the eyes, skin, and respiratory tract. Concentrations of 50 ppm or higher are fatal in 30 minutes; a threshold limit value of 3 ppm has been suggested [304]. For IF_5, a threshold limit value of 2 mg/m^3 is given for an 8-hour workday and 40-hour workweek [305].

Preparation. Chlorine trifluoride is produced on a scale of several hundred tonnes per year by the direct reaction of fluorine with chlorine. The mixture is passed through a nickel tube at ~290 °C; temperature control is necessary because ClF_3 decomposes to F_2 and ClF at high temperatures.

BrF_3 and BrF_5 are manufactured by the gas-phase reaction:

$$Br_2 + xF_2 \longrightarrow 2\,BrF_x \quad x = 3 \text{ or } 5.$$

Several tonnes of BrF_3 are produced per year.

Many methods have been proposed to prepare IF_5. Several hundred tonnes are prepared each year. Fluorination of iodine with AgF, ClF_3, or BrF_3 is used for small-scale preparation. Industrial-scale production often involves the reaction of elemental fluorine with iodine [301]. For example, in a continuous process, 1 % iodine is dissolved in liquid IF_5 and introduced into a reactor in which the fluorination is achieved with fluorine [306].

Chemical Properties and Uses. Like fluorine, halogen fluorides are used for their fluorinating and oxidizing powers. Halogen fluorides such as ClF_3, BrF_3, or IF_5 are fluorinating agents that serve as substitutes for elemental fluorine because their reactions with particular compounds are milder or more specific and because handling is easier. Economy of operation is never claimed, because fluorine is needed for their preparation.

For example, IF_5 has become an important industrial compound because it is an easily storable liquid source of fluorine; it can be used as a solvent and has selective fluorinating properties in organic chemistry.

Metals react with halogen fluorides. In some cases, a passivating fluoride film is formed. Passivation of metallic piping with ClF_3 is used in the nuclear energy field to protect the metal against further corrosion by UF_6. Other possible uses of ClF_3 and BrF_3 in the nuclear energy area are reported: conversion of uranium to UF_6 for

Table 14. Physical properties of halogen fluorides

Compound	M_r	*mp*, °C	*bp*, °C
ClF [*7790-89-8*]	54.45	−155.6	−100.1
ClF_3 [*7790-91-2*]	92.45	− 76.3	11.7
ClF_5 [*13637-63-3*]	130.45	−103	− 13.1
BrF [*13863-59-7*]	98.9	− 33	20
BrF_3 [*7787-71-5*]	136.9	8.8	125.8
BrF_5 [*7789-30-2*]	174.9	− 60.5	41.3
IF_5 [*7783-66-6*]	221.9	9.4	104.5
IF_7 [*16921-96-3*]	259.9	4.5 (subl.)	

isotopic enrichment and recovery of uranium as volatile UF_6 from nuclear fission products, but at present UF_6 is apparently prepared exclusively by the action of F_2 on UF_4 [252].

Halogen fluorides react with many nonmetallic elements except rare gases, nitrogen and oxygen; water is violently decomposed, but dry Pyrex glass is not attacked below 100 °C.

Metallic halides (other than fluorides) react with all halogen fluorides to produce the fluorides and release free halogens. The highest oxidation state of the metal is usually obtained when ClF_3 is used. The fluorinating efficiency decreases in the order $ClF_3 > BrF_5 > IF_7 > ClF > BrF_3 > IF_5 > BrF$ [301]. Thus, only partial replacement of O by F is accomplished when oxides such as P_4O_{10} or WO_3 are dissolved in IF_5, whereas complete replacement of oxygen takes place in the reaction of WO_3 with BrF_3.

ClF_3 and the bromine fluorides react vigorously with organic compounds, leading to mixtures of products. Reactions are controlled more easily with iodine fluorides. Iodine pentafluoride is used on an industrial scale for the production of perfluoroiodoalkanes, which are intermediates in the synthesis of functional perfluoro compounds [252], [307], [308].

Other minor uses of halogen fluorides are mentioned in the literature: ClF_3 has been proposed as an oxidizer for rocket fuels such as hydrazine, but development has not been reported. Intercalation compounds of halogen trifluorides in graphite have been prepared [309]; highly conductive materials are obtained when cis-rich $(CH)_x$ polymer is exposed to IF_5 vapors as a result of doping the polyacetylene film [*25067-58-7*] [310]. During World War II, ClF_3 was used by Germany as an incendiary gas. At the present time the strong oxidizing properties of ClF_3 and BrF_3 are used in an oil-well-tubing cutter [311], [312].

Oxyfluorides of the halogens have been reviewed [313], [314].

6.6. Rare-Gas Fluorides [315–319]

The oxidizing properties of platinum hexafluoride, discovered by Bartlett et al. [320], [321], opened the door to rare-gas chemistry. The first xenon compound was formed by interaction of Xe and PtF_6 vapor at room temperature. Isolable compounds of the heavier gases (krypton, xenon, radon) are known, but work with radon has been limited by its intense radioactivity [319]. Xenon fluorides are prepared by heating mixtures of xenon and fluorine in nickel vessels; high fluorine pressures and low temperatures favor XeF_6 [*13693-09-9*] formation, whereas an excess of xenon leads to a good yield of XeF_2 [*13709-36-9*] [322]. Disproportionation of XeF_2 to XeF_4+ Xe is observed above 623 K.

The preparation of KrF_2 [*13773-81-4*] is carried out at liquid-nitrogen temperature, using a krypton – fluorine mixture irradiated with γ rays or UV radiation. An electrical discharge also gives good results. This fluoride is thermodynamically unstable and must therefore be handled with special care; it is one of the most powerful fluorinators known and serves for the preparation of the highest oxidation states of the elements. For example, it can be used to prepare gold pentafluoride.

The oxidative fluorinating strength increases along the series $XeF_2 < XeF_4 < XeF_6 < KrF_2$ and has been exploited in inorganic chemistry (for example, synthesis of tetravalent lanthanides, preparation of UF_6 from UO_2F_2, UF_4 or UO_3 [323]) and especially in organic chem-

istry [324]. The byproduct is often a noble gas. Graphite intercalation compounds of XeF_4 and XeF_6 have been tested as mild fluorinating agents for aromatic systems. Finally, noble-gas fluorides have been studied for possible uses in high-power lasers [325].

6.7. Graphite Fluorides

The name graphite fluorides is assigned to nonstoichiometric solid fluorocarbons with the general formula $(CF_x)_n$ or $CF_x (0 < x < 1.24)$. The structure of two of these intercalation compounds is known, corresponding to simple F : C ratios: poly(carbon monofluoride) CF [*11113-63-6*] and poly(dicarbon monofluoride) $CF_{0.5}$ [*71183-38-5*]. The general properties of these compounds have been reviewed [326–328].

The industrial product is a grey to white powder that is prepared by direct fluorination of carbon or graphite at 300 – 600 °C [329]. The chemical composition and crystal structure strongly depend on the reaction temperature and the crystallinity of the starting carbons. Graphite fluorides have a very low surface energy. Their conductivity is divided by 10^7 when x increases from 0.3 to 0.5. When $x > 0.5$, the compounds are insulators.

CF is used as a solid lubricant for high temperatures [330], [331], and as a cathodic material for primary Li batteries [332], [333], but carbon black or graphite must be added to the electroactive CF for improving the conductivity. A non-aqueous electrolyte is required, for example $LiBF_4$ or $LiClO_4$ in propylene carbonate or butyrolactone. These cells are now used on a large scale, especially in Japan. Their working voltage (3.2 V) and energy density (300 Wh/kg) are respectively twice and five times that of a conventional carbon/zinc cell.

CF_x/KOH/Zn primary batteries have been patented [334]. A surfactant must be added to insure the wetting of the CF powder by the aqueous electrolyte.

Ternary intercalation compounds of graphite with fluorine and a metallic fluoride such as LiF [*7789-24-4*], AlF_3 [*7784-18-1*], MgF_2 [*7783-40-6*], or CuF_2 [*7789-19-7*] were prepared [335–337]. It was found that some of these have a high electrical conductivity, comparable to that of graphite, and would therefore show a significant potential as new electroconductive materials.

1. Introduction

Organic fluorine compounds are characterized by their carbon – fluorine bond. Fluorine can replace any hydrogen atom in linear or cyclic organic molecules because the difference between the van der Waals radii for hydrogen (0.12 nm) and fluorine (0.14 nm) is small compared to that of other elements (e.g., chlorine 0.18 nm). Thus, as in hydrocarbon chemistry, organic fluorine chemistry deals with a great variety of species. When all valences of a carbon chain are satisfied by fluorine, the zig-zag-shaped carbon skeleton is twisted out of its plane in the form of a helix. This situation allows the electronegative fluorine substituents to envelop the carbon skeleton completely and shield it from chemical (especially nucleophilic) attack. Several other properties of the carbon – fluorine bond contribute to the fact that highly fluorinated alkanes are the most stable organic compounds. These include low polarizability and high bond energies, which increase with increasing substitution by fluorine (bond energies: C – F bond in CH_3F, 448 kJ/mol; C – H bond in CH_4, 417 kJ/mol; C – Cl bond in CH_3Cl, 326 kJ/mol; and C – F bond in CF_4, 486 kJ/mol).

The cumulative negative inductive effect of the fluorine in perfluoroalkyl groups may reverse the polarity of adjacent single bonds (e.g., in the pair $H_3C \lhd I$ and $F_3C \rhd I$) or double bonds (e.g., $CH_3C^{\delta+}H{=}C^{\delta-}H_2$ and $CF_3{-}C^{\delta-}H{=}C^{\delta+}H_2$). Fluorine substitution changes the reactivity of olefins and carbonyl compounds. Polyfluorinated olefins possess an electron-deficient double bond, which reacts preferentially with nucleophiles. Carboxy groups are affected by the presence of an adjacent perfluoroalkyl radical. In carboxylic acids, the acidity is markedly increased. In other carbonyl compounds, the reactivity is increased without any fundamental change in the chemistry of the compound. Correspondingly, the basicity of amines is reduced by the introduction of fluorine. Fluorine attached to the ring of aromatic compounds acts mainly as a para-directing substituent, whereas perfluoroalkyl groups behave as meta-directing substituents.

Naturally, the influence of fluorine is greatest in highly fluorinated and perfluorinated compounds. The fact that these compounds have a high thermal stability and chemical resistance and are physiologically inert makes them suitable for many applications for which hydrocarbons are not. Properties that are exploited commercially include high thermal and chemical stability, low surface tension, and good dielectric properties, for example, in fluoropolymers, perfluorinated oils and inert fluids.

Individual fluorine atoms or perfluoroalkyl groups do not change the technical properties of a hydrocarbon fundamentally. However, this is not the case with physiological properties. A fluorine atom in a bioactive material may simulate a hydrogen atom, and although this does not prevent metabolic processes from occurring, the end products may be ineffective or toxic. Accordingly, such fluorine compounds are important in, for example, pesticides and pharmaceuticals.

A bibliography of the scientific literature of organofluorine chemistry was published in 1986 [16]; commercial applications of fluorine products are reviewed in [7], [17], and [18].

Table 1. Nomenclature of organic fluorine compounds

Formula	CAS registry no.	IUPAC designation	Perfluoro designation
CF_3CF_3	[*76-16-4*]	hexafluoroethane	perfluoroethane, F-ethane
$CF_3CF_2CF_2CHO$	[*375-02-0*]	Heptafluoro-*n*-butyraldehyde	Perfluoro-*n*-butyraldehyde, F-*n*-butyraldehyde
$CF_3(CF_2)_6COOH$	[*335-67-1*]	Pentadecafluoro-*n*-octanoic acid	Perfluoro-*n*-octanoic acid, F-*n*-octanoic acid
$CF_3(CF_2)_2CHF_2$	[*375-17-7*]	1,1,1,2,2,3,3,4,4-Nonafluoro-*n*-butane	1*H*-Perfluoro-*n*-butane, 1-hydryl-F-*n*-butane
$CF_3(CF_2)_4CH_2OH$	[*423-46-1*]	2,2,3,3,4,4,5,5,6,6,6-Undecafluoro-*n*-hexanol	1*H*,1*H*-Perfluoro-*n*-hexanol, 1,1-dihydroperfluoro-*n*-hexanol

Nomenclature. Any organic fluorine compound can be named according to the rules of the International Union for Pure and Applied Chemistry (IUPAC) [19]. However, for highly fluorinated molecules with several carbon atoms, this nomenclature can be confusing. Therefore, the term "perfluoro" may be used when all hydrogen atoms bonded to the carbon skeleton have been replaced by fluorine. The designation of hydrogen atoms belonging to functional groups (e.g., CHO or COOH), of the functional groups themselves, and of other substituents is not affected [19]. Examples are given in Table 1.

In the case of highly fluorinated compounds with few hydrogen atoms (1 – 4), the perfluoro compound can be taken as the parent compound. The hydrogen atoms are named according to their number and position; the letter H or the prefix hydryl (hydro) are used for hydrogen. The symbol F was approved by the American Chemical Society as abbreviation for perfluoro [20].

Historical Development. The pioneering work in organofluorine chemistry dates from 1835 to 1940 [21]. Controlled production of organic fluorine compounds was started in 1892 by exchanging halogen for fluorine in hydrocarbons, using antimony(III) fluoride. The industrial phase began in 1929 in the United States with the discovery of the nonflammable, nontoxic refrigerants CCl_3F and CCl_2F_2 [22]. In Germany, commercial production of aromatic fluorine compounds started in 1930.

The first fluoropolymer, polychlorotrifluoroethylene, was synthesized in 1934 in Germany, followed by the discovery of polytetrafluoroethylene in 1938 in the United States. During World War II, thermally and chemically stable working materials for the separation of uranium isotopes were investigated by the United States Manhattan Project [23]. After World War II, numerous novel applications were discovered. The development of new organic fluorine compounds with novel applications continues undiminished.

2. Production Processes

The four principal methods for the preparation of organic fluorine compounds are as follows [1], [2], [24], [25]:

1) substitution of hydrogen in hydrocarbons using fluorine, high-valency metal or nonmetal fluorides, or electrochemical fluorination
2) halogen – fluorine exchange with hydrogen fluoride, hydrogen fluoride-base complexes, or metal fluorides
3) synthesis of higher molecular mass fluorine compounds from reactive fluorinated synthons
4) addition of fluorine, hydrogen fluoride, or reactive nonmetal fluorides to unsaturated bonds

Only a few of the many possibilities in each group have been developed commercially, with varying degrees of success.

2.1. Substitution of Hydrogen

Fluorination with Elemental Fluorine [26], [27]. The action of elemental fluorine on organic compounds normally leads to violent, mainly explosive, reactions. The substrate fragments into units with a varying degree of fluorination because the heats of formation of the

C – F bond (ca. 460 kJ/mol) and the H – F bond (566 kJ/mol) are greater than the heat of formation of the C – C bond (ca. 348 kJ/mol).

Therefore, direct fluorinations must take place with strict control of the reaction and removal of the heat generated. This may be achieved by dilution of the fluorine with inert gases (e.g., N_2 or CO_2), dilution of the organic substrates with inert solvents [28], intensive mixing, and reduction of the temperature to as low as − 150 °C.

Direct fluorination can also be carried out in the gas phase in a tubular reactor packed with silver- or gold-plated copper turnings [29]. Specialized methods are based on LaMar fluorination [26], aerosol fluorination [30], porous-tube fluorination [31], and jet fluorination [32]; high product selectivities are achieved at a laboratory scale. Commercial operation remains to be developed.

Fluorination with Metal Fluorides [33]. Metal fluorides that can transfer fluorine to organic substrates by changing the oxidative state of the metal, such as cobalt(III) fluoride (CoF_3) and silver(II) fluoride (AgF_2), serve as fluorinating agents in an oxidizing fluorination. The spent metal fluoride is regenerated with elemental fluorine.

Fluorination and regeneration can be cyclical, permitting a commercial operation.

Electrochemical Fluorination. The *Simons process* [34], [35] is used commercially for the production of perfluorinated compounds. Solutions of organic compounds (mainly carboxylic acids, sulfonic acids, and tertiary amines) are electrolyzed in anhydrous hydrogen fluoride in a single cell without intermediate formation of free fluorine. Fluorination takes place at a nickel anode by a free-radical mechanism at current densities of 10 – 20 mA/cm^2 [36]. Selectivity decreases sharply as the number of carbons increases.

Volatile, hydrogen-containing compounds (hydrocarbons and chlorohydrocarbons) can be electrofluorinated on porous graphite anodes in KF-containing hydrogen fluoride in a process developed by Phillips Petroleum [37], [38], [39] and now referred to as CAVE (Carbon Anode Vapor Phase Electrochemical Fluorination), in operation at 3 M [40]. The organic compound is introduced into the cell through the anode. In the pores of the anode, i.e., at the phase boundary, partial or complete exchange of the hydrogen, but not the chlorine, takes place. To date this process has been used only on a small scale.

2.2. Halogen – Fluorine Exchange

Exchange of chlorine with hydrogen fluoride is used in many commercial processes both for the production of chlorofluoroalkanes and for the side-chain fluorination of aromatic and *N*-heterocyclic compounds [41]. The method involves exchange of chlorine for fluorine in polyhalogenated compounds using hydrogen fluoride [42]:

Whether the process takes place with or without a catalyst depends on the reactivity of the chlorine atoms to be exchanged. With compounds containing several chlorine atoms of differing reactivity, selective fluorination can be achieved by selecting suitable process conditions.

Fluorinations without a catalyst such as

are carried out in liquid, anhydrous hydrogen fluoride at 100 – 150 °C in pressure vessels made of steel, alloy steels, or nickel. The process can be carried out by batch (e.g., autoclave) or continuous methods (autoclaves in series or a tubular reactor). In either case, the hydrogen chloride that is generated during fluorination is removed from the reactor to maintain the desired pressure.

Most liquid-phase fluorinations, e.g., of CCl_4, $CHCl_3$, CCl_3CCl_3, CCl_3CHCl_2, or CCl_3CH_2Cl, are carried out in the presence of a catalyst [43] to promote the exchange, which becomes increasingly difficult as fluorination progresses. The main catalysts used are antimony(III) and antimony(V) halides with low

volatility. Addition of chlorine oxidizes the antimony to the pentavalent state.

In addition to the liquid-phase processes, many commercially important gas-phase fluorinations employ hydrogen fluoride [43]. The components in the gas phase are passed through a tubular reactor containing the catalyst. The composition of the product can be controlled within wide limits by varying temperature, pressure, residence time, catalyst, and the proportions of the reactants. Various metal fluorides are suitable catalysts, e.g., aluminum fluoride [44] or basic chromium fluoride [45].

For further processing of the mixture produced by gas- or liquid-phase fluorination, the following criteria should be satisfied [46]:

1) The hydrogen chloride generated should be separated in a pure form to permit further use.
2) Unreacted hydrogen fluoride should be recovered.
3) Acid residues, water, and other impurities must be removed from the product.

Usually, the hydrogen chloride is separated from the crude fluorination mixture by fractional distillation. The bulk of the hydrogen fluoride may then be separated from the residue. Further treatment includes washing to remove traces of acid, drying, and fractional distillation.

Exchange of Chlorine with Nonoxidizing Metal Fluorides [41]. Alkali fluorides, especially potassium fluoride, are often used to exchange chlorine in carboxylic acid chlorides, sulfonic acid chlorides, α-chlorocarboxylic acid derivatives (esters, amides, and nitriles), aliphatic monochloro compounds, or activated aromatic chloro compounds (Halex process) [47].

The dry, finely powdered metal fluoride is employed in a solvent-free process at 400–600 °C, e.g., with polychlorinated aromatic compounds, or, in most other cases, in the presence of a solvent. For slow reactions, polar, aprotic solvents are used.

2.3. Synthesis from Fluorinated Synthons

The variety of organic fluorine compounds can be greatly increased by the use of easily accessible, low molecular mass fluoroalkanes and olefins to synthesize higher molecular mass products. Halofluoromethanes add to halogenated ethylenes to form halogenated fluoropropanes [48]. An industrially applied reaction is the addition of iodopentafluoroethane to tetrafluoroethylene yielding a homologous series of long-chain 1-iodoperfluoroalkanes (see Section 3.4). The pyrolysis of chlorodifluoromethane is the industrial source of tetrafluoroethylene, hexafluoropropene, and the corresponding oligomers and polymers (see Sections 4.1 and 4.2). These examples illustrate the importance of this synthetic method, especially for the production of organic fluorine compounds containing more than two carbon atoms where the above-mentioned fluorination methods fail to give high yields of the desired products.

2.4. Addition of Hydrogen Fluoride to Unsaturated Bonds

Addition of hydrogen fluoride to alkenes and alkynes takes place below 0 °C with formation of mono- or difluoroalkanes; ethylene and acetylene are exceptions [24]. Ethyl fluoride is produced from ethylene and hydrogen fluoride at 90 °C; catalytic processes have been developed for the addition of hydrogen fluoride to acetylene to produce vinyl fluoride or 1,1-difluoroethane. Unsymmetrical olefins obey Markovnikov's rule. Chloroolefins can undergo chlorine – fluorine exchange after addition of hydrogen fluoride. Addition of hydrogen fluoride to the electron-deficient double bond of perfluoroolefins can be performed using trialkylamine trishydrofluorides at moderate temperatures [49].

2.5. Miscellaneous Methods

Substitution of Amino Groups in Aromatic Compounds [50]. Introduction of one or two fluorine atoms into aromatic rings is carried out commercially by diazotization of aromatic amines in anhydrous hydrogen fluoride with solid sodium nitrite and decomposition of the dissolved diazonium salt (see Section 11.1.2).

Fluorination with Nonmetal Fluorides. Reactions of nonmetal fluorides with certain substrates are predominantly restricted to laboratory operations. Sulfur tetrafluoride and the following compounds can be used for the controlled introduction of fluorine into organic compounds: dialkylaminosulfur(IV) fluorides (R_2NSF_3) [51–53], fluoroalkylamines (e.g., 2-chloro-1,1,2-trifluoroethyldiethylamine or 1,1,2,3,3,3-hexafluoropropyldiethylamine), tetra-*n*-butylammonium fluoride, trialkylamine trishydrofluorides, nitrosyl fluoride, perchloryl fluoride, fluoroxyfluoroalkanes (e.g., CF_3OF) [54], xenon difluoride [55], or CH_3COOF [56]. They are of commercial value for the fluorination of complex organic compounds such as pharmaceuticals.

2.6. Purification and Analysis

Impurities are usually removed from organic fluorine compounds by fractional distillation, fractional crystallization, or chromatographic methods. This does not apply to fluoropolymers and high-boiling perfluorinated oils, which require special measures, i.e., the use of extremely pure starting materials.

Quantitative determination of fluorine is possible in most cases by combustion and subsequent analysis of the hydrogen fluoride generated. Wet chemical methods are used to determine fluoride ions [57].

Because of the high volatility of organic fluorine compounds, purity can be readily determined by gas chromatography. ^{19}F-Nuclear magnetic resonance spectroscopy is a valuable tool for determining the structure of organic fluorine compounds. Structure determinations, even of mixtures, are often easier using this method than with ^{1}H-NMR spectra due to the larger chemical shifts of ^{19}F-NMR spectra. The ^{19}F signals can be integrated and used for quantitative analysis [58].

3. Fluorinated Alkanes

The hydrogen atoms of alkanes may be partially or totally replaced by fluorine. Partially fluorinated alkanes are hydrofluorocarbons (HFCs); fully fluorinated alkanes (perfluoroalkanes) are perfluorocarbons (PFCs). In chlorofluorocarbons (CFCs) and hydrochlorofluorocarbons (HCFCs), the alkane hydrogens are replaced by both chlorine and fluorine.

A special nomenclature [59] has been introduced to identify smaller chain length fluoroalkanes (up to four carbon atoms) used in refrigerants. It consists of a three-digit number combined with various letters. The first figure of the three-digit number indicates the number of carbon atoms minus one (for methane derivatives, the figure 0 is omitted); the second figure indicates the number of the hydrogen atoms plus one; and the third figure indicates the number of fluorine atoms. All other bonds are saturated with chlorine. The letter R before the code number is an abbreviation for refrigerant; the letter C indicates a cyclic compound. The complete number is called the refrigerant number. The American Society of Heating, Refrigerating, and Air Conditioning Engineers (Atlanta, Georgia) ASHRAE Standard 34 – 78 describes the method of coding. The abbreviation F is sometimes used and stands for fluorohydrocarbon.

This system does not allow isomerisms to be expressed for ethane derivatives; for such cases, a letter (a, b, . . . etc.) is added to isomers as their asymmetry increases, e.g.,

$CF_2Cl-CCl_2F$ = CFC 113 (R 113)
CF_3-CCl_3 = CFC 113 a (R 113 a)

The compound with the highest degree of symmetry is not given a letter.

A special isomer in the series of propane derivatives is designated by adding two letters to the numbers derived from the standard rules [60]. The first letter attached to the number refers to the central carbon atom, coding the total atomic mass of the two substituents attached (a = CCl_2, b = CFCl, c = CF_2, d = CHCl, e = CHF, f = CH_2). The second appended letter is derived from the symmetry rule applied to the two terminal carbon atoms combined to an imaginary ethane unit. This unit is then treated like an ethane derivative with the difference that the letter a is given to the most symmetric combination. Examples for the codes of the isomeric propane derivatives $C_3HCl_2F_5$ are:

$CF_3–CF_2–CHCl_2$	HCFC 225 ca
$CF_2Cl–CF_2–CHFCl$	HCFC 225 cb
$CF_3–CHCl–CF_2Cl$	HCFC 225 da
$CF_3–CHF–CFCl_2$	HCFC 225 eb.

Codes for the butane derivatives contain three letters appended to the numeral (e.g., $CF_3–CH_2–CF_2–CH_3$ is coded as HFC 365 mfc [61]).

3.1. Fluoroalkanes and Perfluoroalkanes

Properties. *Monofluoroalkanes* are attacked by bases and sometimes by heat; however, chemical resistance increases with increasing fluorine substitution, especially multiple substitution at the same carbon atom.

Perfluoroalkanes have distinct properties [62], [63]. Their physical properties differ from those of the corresponding hydrocarbons: densities and viscosities are higher, whereas surface tensions, refractive indices, and dielectric constants are lower. At room temperature perfluoroalkanes are attacked only by sodium in liquid ammonia. At 400 – 500 °C, they are degraded by alkali metals and silicon dioxide; the former produce a metal fluoride and carbon, while the latter produces silicon tetrafluoride and carbon dioxide. Thermal decomposition starts above 800 °C (compounds with tertiary carbon atoms above 600 °C) with the formation of saturated and unsaturated decomposition products and some carbon. In addition to their chemical and physical stability, perfluoroalkanes are characterized by nonflammability and physiological inertness.

Whereas partially fluorinated alkanes dissolve in many common solvents, perfluoroalkanes have low solubility, which decreases with their chain length. Only ethers, ketones, esters, chlorohydrocarbons, and chlorofluorocarbons have the power to dissolve perfluoroalkanes [62]. Boiling points, melting points, and densities of fluoroalkanes and perfluoroalkanes are listed in Table 2. For other physical properties of HFCs, see Table 3. Physical data for liquid perfluoralkanes are given in Tables 4 and 5.

Production. Mono- and difluoroalkanes can be produced by addition of hydrogen fluoride to olefins or alkynes (e.g., $CF_2H–CH_3$, HFC 152 a). Another synthetic pathway is the exchange of chlorine (or bromine) for fluorine using hydrogen fluoride or metal fluorides such as antimony fluoride. Monohydroperfluoroalkanes can be obtained by adding hydrogen fluoride to perfluoroalkenes (e.g., $CF_3–CHF–CF_3$, HFC 227 ea) or by decarboxylation of perfluorocarboxylates in the presence of proton donors. The novel commercially interesting hydrofluorocarbons are produced by processes, that have been developed for the production of chlorofluorocarbons and hydrofluorocarbons and optimized during the last decades (see Section 3.2).

Higher temperatures and higher hydrogen fluoride : substrate ratios are necessary to achieve complete replacement of all chlorine atoms in the starting chlorocompounds by fluorine. Both liquid-phase halogen exchange in the presence of catalysts such as antimony(V) or tin(IV) chlorofluorides and vapor phase reactions using solid-phase catalysts based on chromium are employed. Preferred starting materials are chloroform for HFC 23 [45], [65], dichloromethane for HFC 32 [66] and 1,1,1-trichloroethane for HFC 143 a [67]. The conversion of tetrachloroethylene to HFC 125 [68] and trichloroethylene to HFC 134 a [69] involves initial HF-addition across the double bond followed by a series of chlorine – fluorine exchange reactions. Vapor-phase hydrogenolysis of chlorofluorocarbons and hydrochlorofluorocarbons is also proposed for the production of hydrofluorocarbons [70], [71].

Perfluoroalkanes can be produced by a variety of routes. Indirect fluorination of hydrocarbons with cobalt(III) fluoride or silver(II) fluoride is carried out in a steel or nickel tube with stirring. The hydrocarbon vapors are passed at 150 – 450 °C over the fluorinating agent, which is regenerated in a fluorine stream [72], [73]. This process is suitable for the production of perfluoroalkanes containing up to 20 carbon atoms. It affords better process control and yields than the direct gas-phase fluorination using dilute fluorine and a metal catalyst, especially for longer-chain compounds [74].

Fluoroalkanes and perfluoroalkanes can also be produced electrochemically by the Phillips Petroleum process or the electrochemical fluorination of alcohols, amines, carboxylic acids, and nitriles by the Simons process (see Section 2.1).

Table 2. Boiling points, melting points, and densities of fluoroalkanes and perfluoroalkanes

Compound	CAS registry no.	Formula	M_r	Refrigerant no.	Code no.	*bp*, °C	*mp*, °C	d_4^θ, g/cm^3 (θ, °C)

Tetrafluoromethane (carbon tetrafluoride, CF_4) can be produced by reaction of CCl_2F_2 or CCl_3F and hydrogen fluoride in the gas phase [75] or by direct fluorination of carbon [76]. Hexafluoroethane (PFC 116) is often obtained as a byproduct in the production of CFC 115. Octafluoropropane (PFC 218) can be produced by direct [77], electrochemical [78], or CoF_3-fluorination [79] of commercially available hexafluoropropene (see Section 4.2). Octafluorocyclobutane is obtained by dimerization of tetrafluoroethylene [80] or by passing 1,2-dichloro-1,1,2,2-tetrafluoroethane, $CClF_2CClF_2$, over a nickel catalyst at 590 °C [81].

Uses. Hydrofluorocarbons have been gaining increasing commercial interest as substitutes for chlorofluoro- and hydrochlorofluorocarbons since governmental regulations banned the worldwide production and consumption of CFCs by 1996 and introduced a specific timetable for the phase out of HCFCs [82]. In contrast \011to CFCs hydrofluorocarbons have no adverse effect on the ozone layer and only a low contribution to global warming (see below). The latter effect could be further minimized by avoiding leakages in refrigeration and air-conditioning equipment and by refrigerant recycling.

In all applications involving considerable emissions to the atmosphere, e.g., as propellants in aerosols (except medicinal aerosols), in open cell foams, or in extruded foams CFCs will be replaced by nonhalogenated compounds in the future.

Due to the presence of hydrogen in the molecule, the stability of HFCs is reduced. In the atmosphere they are degraded below the stratospheric level, leading to zero ozone depletion potentials (ODP = 0) and to reduced halogen global warming potentials (HGWPs). However, depending on the structure of the HFCs this re-

duced stability can entail an increased flammability and thus make safe handling more difficult. Therefore, alternatives to the CFCs need to retain the attractive properties of CFCs like low toxicity, nonflammability, good thermodynamic properties, and accessibility via economically and ecologically viable manufacturing processes, but avoid any adverse effect to the environment.

In refrigeration and air-conditioning systems CFC 12 is replaced by HFC 134 a, HCFC 22 by the azeotropic mixtures HFC 507 (HFC 125/HFC 143 a 1 : 1) or HFC 410 (HFC 32/HFC 125 1 : 1) and CFC 13 by HFC 23. HFC 134 a and HFC 227 ea can be used as propellants in medicinal aerosols instead of CFC 114. HFC 245 fa and HFC 365 mfc are proposed as blowing agents for foams in replacing CFC 11, CFC 113 and HCFC 141 b [83]. Until now no HFC candidate for replacement of CFC 11 and CFC 113 as solvents, degreasing agents, or cleaning agents for textiles or metal surfaces has been identified. In the period 1990–1995 159.5 x 10^3 t of HFC 134 a have been produced [84].

Gaseous perfluorocarbons (PFC 14, PFC 116, PFC 218) are used in plasma etching processes in the microelectronic industry [85] and as gaseous dielectrics. Liquid perfluorocarbons [64] serve as heat-transfer media in transformers and in capacitors, as lubricants and hydraulic fluids, or in vapor-phase soldering [86] and vapor-phase sterilization [64].

Perfluoroalkanes, e.g., perfluorodecalin [*306-94-5*], are used in the production of blood substitutes [87].

Trade Names. Hydrofluorocarbons substituting chlorofluorocarbons and hydrochlorofluorocarbons are marketed worldwide under protected trade names. The individual product is characterized by the HFC code number following the trade name. Some worldwide applied trade names are:

France	
Rhône-Poulenc	Isceon
Elf Atochem	Forane
Germany	
Hoechst	Reclin
Solvay	Solkane
United Kingdom	
ICI	Klea
Italy	
Montefluos	Algogrene
Japan	
Asahi Glass	Asahiflon
Daikin	Daiflon
United States	
Allied Signal	Genetron
DuPont	Suva
Great Lakes Chemical	FM
3 M	3M Brand

Perfluorocarbons are offered under trade names such as Freon C-51-12; Perfluorokerosene FCX-329, FCX-330;Perfluorolube oil FCX-512, FCX-412 (DuPont); Flutec PP-1, PP-2, PP-3, PP-9, etc. (BNFL Fluorochemicals), Multifluor Inert Fluids (Air Products and Chemicals).

3.2. Chlorofluoroalkanes

For more than 50 years chlorofluorocarbons and hydrochlorofluorocarbons have been the most important organic fluorine compounds commercially. The five products listed in Table 6 have been by far the most important of these with regard to the field of applications and to the amount produced [84].

Table 6. Economically most important organic fluorine compounds

Compound	Total production through 1995, 10^6 t	Maximum annual production (year), 10^3 t
Trichlorofluoromethane (R 11, CFC 11)	8.62	382 (1987)
Dichlorodifluoromethane (R 12, CFC 12)	11.28	425 (1987)
Chlorodifluoromethane (R 22, HCFC 22)	3.85	243 (1995)
1,2,2-Trichloro-1,1,2-trifluoroethane (R 113, CFC 113)	2.97	251 (1989)
1,2-Dichloro-1,1,2,2-tetrafluoroethane (R 114, CFC 114)	0.51	19 (1986)

The results of the investigation on postulated atmospheric changes caused by CFCs [88] with respect to the ozone balance and the greenhouse effect [89], [90] verified the adverse impact on the stratospheric ozone layer and the significant contributions to global warming due to the long atmospheric lifetimes of the CFCs. In 1987, a United Nations agreement, called the Montreal Protocol – revised in 1992 during the Copenhagen Intergovernmental Conference – set the deadline for the phase out of CFCs in developed countries. Since 1996 production and consumption of CFCs are prohibited, except as intermediates in the production of fluorine chemicals, especially fluoropolymers. For HCFCs with reduced atmospheric stabilities a timetable has been introduced for their phase out. HCFCs are allowed to be used as drop-in alternatives for CFCs until suitable HFC substitutes (see Section 3.1) will have been developed, but no longer than until 2015 to 2030 [82].

High molecular mass chlorofluorocarbons, a small but significant class of CFCs will not be affected by the ban.

Properties. Chlorofluoroalkanes are characterized by high chemical and thermal stabilities, which increase with their fluorine content. Low flammability (or nonflammability) and low toxicity are additional commercial advantages. Most of these compounds have a pleasant, weak odor; some are mild anesthetics [91].

Boiling points, freezing points, and densities of formerly commercially important chlorofluoroalkanes are shown in Table 7; other physical properties are listed in Table 8. Physical properties of some high molecular mass CFCs produced from chlorotrifluoroethylene are given in Table 9.

Production. Commercial production of chlorofluoroalkanes employs halogen exchange, with hydrogen fluoride in the liquid phase in the presence of a catalyst. The production scheme for dichlorodifluoromethane shown in Figure 1 is typical [93]:

$$CCl_4 + 2\,HF \longrightarrow CCl_2F_2 + 2\,HCl$$

A steam-heated steel autoclave (a) lined with stainless steel (V2A) serves as the reactor. The seals are made from aluminum or copper. The autoclave (capacity $2-5\,m^3$) is filled with 500 kg of hydrogen fluoride, 1540 kg of car-

bon tetrachloride, 220 kg of antimony(III) chloride, and 20 kg of chlorine, and the mixture is heated to 100 °C. After ca. 2 h and an increase in pressure to ca. 3 MPa, the fluorination products with lower boiling points are removed together with the hydrogen chloride that is generated and some hydrogen fluoride; higher-boiling products in the exit gases are condensed and recycled. The low-boiling fraction is first washed with water in a tower (e) lined with poly(vinyl chloride) and packed with graphite; it is then washed with caustic in a tower (f) filled with porcelain packing. After being washed to neutrality, the product is dried in a tower (i) containing concentrated sulfuric acid, compressed to a liquid, and fed into an intermediate storage tank (m). Each batch takes ca. 24 h to process. The antimony catalyst remains in the reactor and is regenerated before each subsequent batch by adding a small amount of chlorine to convert it to the catalytically active Sb(V) form.

The crude product is fractionally distilled under pressure (0.6 – 0.8 MPa). The lower-boiling fraction contains some chlorotrifluoromethane and most of the dichlorodifluoromethane (yield 90 % based on carbon tetrachloride, 80 % based on hydrogen fluoride). The higher-boiling fraction consists of trichlorofluoromethane (5 – 10 % based on carbon tetrachloride), which can be recycled. The distilled product is passed through a caustic filter (s). Steel bottles, pressure vessels, tank cars, and tank trucks are used for transport.

More recently developed exchange processes are carried out continuously in the gas phase at 100 – 400 °C, using catalysts based on chromium [45], aluminum [44], or iron [94]. Starting materials, which include carbon tetrachloride, chloroform, tetrachloroethylene, and trichloroethylene, are passed over the catalyst with excess hydrogen fluoride and, where necessary, chlorine. Further processing follows the same principles as in the liquid-phase process.

In the Montedison chlorofluorination process, reaction of C_1- and C_2-hydrocarbons with chlorine and hydrogen fluoride takes place in a single step in a fluidized-bed reactor. A suitable catalyst is a combination of aluminum chloride and other metals [95–97]:

$$CH_4 + 4\,Cl_2 + 2\,HF \xrightarrow{\text{Cat.}} CCl_2F_2 + 6\,HCl$$

Commercial production of chlorofluoroalkanes is also possible by the electrochemical fluorination process developed by Phillips Petroleum (see Section 2.1).

High molecular mass chlorofluoroalkanes are produced by fluorination with chlorine trifluoride [98], [99].

Other important processes for production of high molecular mass CFCs are based on the telomerization of chlorotrifluoroethylene (see Section 4.7) with carbon tetrachloride [100] or CFC 113 [101] as telogens. Stabilization and end-group fluorination are achieved using cobalt trifluoride as fluorinating agent [102], [103].

Specifications. Chlorofluoroalkanes (and also the alternative HCFCs and HFCs) produced on an industrial scale are subject to stringent standards. Impurities must not exceed the following limits (vol %):

acids	0
moisture	< 0.001
higher-boiling fractions	< 0.05
other gases	2

Uses. Up to the ban in the USA in 1978 chlorofluoroalkanes had been used mainly as aerosol propellants and as spraying and foam blowing agents (R 11, R 12, R 114). Further important applications up to 1996 had been in the area of refrigerants, where R 11, R 12, R 13, R 22, R 113, R 114, R 115, and the chlorine-free compounds R 23 and RC 318 were preferred. Of the drop-in

alternatives to CFCs HCFC 22 is the most important compound, used as refrigerant (annual production in 1995 243×10^3 t [84]), followed by HCFC 141 b (113×10^3 t in 1995 [84]) and HCFC 142 b (38×10^3 t in 1995 [84]) used as blowing agents for closed cell foams. For HFCs as alternatives see Section 3.1.

Chlorofluoroalkanes, especially R 11 and R 113, were also employed as solvents and degreasing and cleaning agents for textiles; HCFC 22, CFC 113, and HCFC 142 b will be important intermediates for the production of fluoroolefins also in the future.

Higher molecular mass perchlorofluoroalkanes are used as oils, greases, and waxes, as lubricants, hydraulic fluids, damping oils, heat-transfer media, impregnating agents, and plasticizers. Oligomers of chlorotrifluoroethylene have achieved special importance in this area [104].

Trade Names. Chlorofluoroalkanes were sold worldwide under protected trade names; the refrigerant numbers describing the chemical composition (see Table 7) are included to specify individual compounds. Some of the trade names that were applied worldwide are:

Australia	
Australian Fluorine Chemicals	Isceon
Czechoslovakia	
Slovek Pro Chemickov	Ledon
Federal Republic of Germany	
Hoechst	Frigen
Kali-Chemie	Kaltron

Trade names of higher molecular mass chlorofluoroalkanes include Florubes (ICI), Fluorolube oils, Fluorolube greases (Hooker Industrial Chemicals Division),Halocarbon oils, greases, and waxes (Halocarbon Products),Kel-F oils, greases, and waxes (3M), and Voltalef (Atochem).

3.3. Bromofluoroalkanes

Bromofluoro compounds of practical importance are found mainly in the methane and ethane series.

In the refrigerant (R) numbering system for bromofluoroalkanes, the corresponding chlorofluoroalkanes are taken as the basic structures (see also Section 3); the substitution of chlorine by bromine is expressed by the addition of B1, B2, etc. For example, bromotrifluoromethane is denoted as R 13B1 and 1,2-dibromotetrafluoroethane as R 114B2. In firefighting applications the Halon numbering system is used, specifying the number of carbon, fluorine, chlorine, and bromine atoms in the molecules when reading from left to right (e.g., Halon 1301 denotes CF_3Br; Halon 1211 is CF_2ClBr; and Halon 2402 denotes CF_2BrCF_2Br).

Bromofluorocarbons (BFCs) and hydrobromofluorocarbons (HBFCs) are involved in the depletion of stratospheric ozone and global warming like the CFCs and HCFCs; however the contributions of the bromine-containing compounds are distinctly higher. Therefore, the 1992 Copenhagen meeting agreed to phase out the production of BFCs and HBFCs by 1994, with the exception of Halon for some essential firefighting applications. HFC 125 and HCFC 123 (DuPont) or HFC 227 ea (Great Lakes) are announced as alternatives though they are significantly less efficient as fire extinguishing agents than the BFC Halons

Properties. Fully halogenated compounds with a high fluorine content have excellent thermal stability; they are nonflammable and some

(e.g., CF_3Br) are physiologically inert [92]. At high temperature, thermal cleavage of the C–Br bond into radicals occurs, which is responsible for the utility of some of these compounds in extinguishing fires (→ Fire Extinguishing Agents, Chap. 6.) [105]. Their chemical stability is slightly lower than that of the corresponding chlorofluoroalkanes. However, as with the chlorofluoroalkanes, stability increases with the fluorine : bromine ratio. Some compounds have a marked anesthetic effect [91]. Physical properties are listed in Table 10.

Production. Bromofluoromethanes are obtained by bromination of a stream of the appropriate fluoromethane [106] or chlorofluoromethane [107] at 300–600 °C. Ethane derivatives can also be obtained by thermal bromination [108] or by addition of bromine or hydrogen bromide [109] to fluoroolefins. In some cases hydrogen bromide can be used to exchange a chlorine atom in a chlorofluoroalkane for a bromine atom [110]. Iodine–bromine exchange in a fluoroiodoalkane can be effected with bromine [111].

Uses. The lower-boiling compounds $CBrF_3$ (R 13B1; Halon 1301) and $CBrClF_2$ (R 12B1; Halon 1211) had been used as fire extinguishing agents. Producers were Atochem, ICI, and Solvay in Europe, DuPont and Great Lakes in the USA and Asahi Glass, Daikin, and Nippon Halon in Japan. The total worldwide Halon production was estimated to be 25×10^3 t in 1986.

Perfluoro-1-bromo-*n*-octane [*423-55-2*] is physiologically inert and is useful as an X-ray contrast agent, especially for lung examinations [112]. With its low surface tension it penetrates small spaces and evenly wets healthy lung tissue.

2-Bromo-2-chloro-1,1,1-trifluoroethane [*151-67-7*], also known as halothane, has been used worldwide since 1956 as an effective, nonflammable inhalation anesthetic (→ Anesthetics, General). It is commonly produced by the ICI process:

$$CF_3CH_2Cl \xrightarrow[-HBr]{Br_2} CF_3CHBrCl$$

or the Hoechst process [43, pp. 208–210]:

$$CF_2{=}CClF \xrightarrow[h\nu]{+HBr} CBrF_2CHClF \xrightarrow{Cat.} CF_3CHBrCl$$

As alternatives for halothane a series of fluorinated ethers (containing in addition hydrogen and chlorine atoms or exclusively hydrogen atoms) have been developed, that retain or even surmount the desirable properties of halothane as inhalation anesthetic [113]. However, also these compounds have an adverse effect on the ozone layer.

Trade Names. Fluothane (ICI), Halothane "HOECHST" (Hoechst).

3.4. Iodofluoroalkanes

Iodofluoroalkanes have become important intermediates in the commercial production of compounds containing a perfluorinated moiety.

Properties. In contrast to chloro- and bromofluoroalkanes, iodofluoroalkanes readily undergo chemical reactions [24, Chap. 6], reacting preferentially by homolytic cleavage of the C–I bond.

The radical intermediates $C_nF_{2n+1}^{\bullet}$ and $I^{\bullet}$ can add to double bonds; thus, reaction with ethylene yields 1*H*,1*H*,2*H*,2*H*-1-iodoperfluoroalkanes, which are commercially important intermediates [114]:

$$C_nF_{2n+1}I + CH_2{=}CH_2 \longrightarrow C_nF_{2n+1}CH_2CH_2I$$

Control of the reaction between iodofluoroalkanes and fluoroolefins, especially tetrafluoroethylene, can result in oligomerization (telomerization) of the olefin [115]:

$$CF_3I + n\,CF_2{=}CF_2 \longrightarrow CF_3(CF_2CF_2)_nI$$

This reaction is employed commercially and is initiated by free radicals, UV irradiation, or heat [116].

Iodofluoroalkanes also form organometallic compounds, some of which are useful intermediates, e.g., for Grignard reactions [117].

Iodoperfluoroalkanes cannot be used as alkylating agents and their applications are therefore limited. However, derivatives of the FITS-type reagent are alkylating agents [118]:

FITS reagent (perfluoroalkyl)phenyliodonium triflate

Physical constants of some iodofluoroalkanes are shown in Table 11.

Production. Iodofluoroalkanes can be produced by heating the silver salts of the perfluorocarboxylic acids with iodine [119] or the corresponding sodium salts with iodine in dimethylformamide [120]. Of commercial importance is the production of pentafluoroiodoethane (CF_3CF_2I) by reaction of tetrafluoroethylene with a mixture of iodine pentafluoride and iodine [121]:

$$5\,CF_2{=}CF_2 + IF_5 + 2\,I_2 \longrightarrow 5\,CF_3CF_2I$$

Heptafluoro-2-iodopropane (CF_3CFICF_3) is obtained similarly from hexafluoropropene.

The higher homologues $C_nF_{2n+1}I$ ($n = 4$ – 12) are produced commercially by reaction of the lower members with tetrafluoroethylene (telomerization).

α,ω-Diiodoperfluoroalkanes are obtained from tetrafluoroethylene and iodine [122]:

$$I_2 + CF_2{=}CF_2 \longrightarrow ICF_2CF_2I \xrightarrow{CF_2=CF_2} I(CF_2CF_2)_nI$$

Uses. 1-Iodoperfluoroalkanes and 1*H*,1*H*,-2*H*,2*H*-1-iodoperfluoroalkanes are intermediates in the production of surfactants and textile finishes [123]. Perfluorocarboxylic acids, especially perfluorooctanoic acid, are obtained from perfluoroiodoalkanes [124], and perfluori-

nated dicarboxylic acids are obtained from α,ω-diiodoperfluoroalkanes [125].

4. Fluorinated Olefins

The commercial importance of fluoro- and chlorofluoroolefins lies in the production of fluorinated plastics and inert fluids.

Properties. The chemical behavior of fluoroolefins [126] is governed by the number of vinylic fluorine atoms. In contrast to their hydrocarbon analogues, fluoroolefins are attacked by electrophiles only with difficulty [127], which increases with the degree of fluorination. However, fluoroolefins react readily with nucleophiles [128], [129], because as the number of vinylic fluorine atoms increases, the π-electron system of the double bond is destabilized. Thermodynamic calculations have shown that the strength of the C – C π-bond in tetrafluoroethylene

$$CF_2{=}CF_2 \rightleftharpoons {}^{\bullet}CF_2{-}CF_2^{\bullet}$$

is only ca. 160 kJ/mol as opposed to 241 kJ/mol in ethylene [130]. In unsymmetrically substituted fluoroolefins, the nucleophile attacks the carbon atom that is made strongly positive by the neighboring fluorine atoms and is shielded only weakly (sp^2 hybridization). The reactivity of fluoroolefins toward nucleophiles increases as follows:

$$CF_2{=}CF_2 < CF_2{=}CF{-}CF_3 < CF_2{=}C(CF_3)_2$$

Fluoroolefins are slightly to highly toxic and must be handled with care. The toxicity of fluorinated olefins is apparently proportional to their reactivity toward nucleophiles [131]. Perfluoroisobutene, $CF_2{=}C(CF_3)_2$ [*382-21-8*], for example, is far more toxic than its lower homologues.

Physical properties of commercial fluoro- and chlorofluoroolefins are given in Table 12.

Fluoroolefins also differ from hydrogen-containing olefins in their marked tendency to undergo cycloaddition [132].

Production. Fluoroolefins are produced by dehalogenation of chlorofluoro-, bromofluoro-, or iodofluoroalkanes with zinc and alcohol, by dehydrohalogenation of hydrogen-containing haloalkanes with alcoholic alkali, or by heating. Other common methods include addition of hydrogen halides to alkynes, decarboxylation of fluorocarboxylic acid salts, and pyrolysis of fluorohydrocarbons [133–135].

4.1. Tetrafluoroethylene

Properties. Tetrafluoroethylene (TFE), perfluoroethylene, $CF_2{=}CF_2$, a colorless, odorless gas, is flammable in oxygen, producing tetrafluoromethane and carbon dioxide. For physical properties, see Table 12. At low temperature in the presence of oxygen, explosive peroxides are formed [136], [137]. Tetrafluoroethylene must be handled with great care since, even in the absence of oxygen, it can decompose explosively into carbon and tetrafluoromethane under pressure above $-20\,°C$ ($\Delta H = -276$ kJ/mol at 298 K). If the polymerization to polytetrafluoroethylene (PTFE) ($\Delta H = -172$ kJ/mol at 298 K) is uncontrolled, a more strongly exothermic decomposition reaction can occur. Polymerization inhibitors include dipentene [*138-86-3*], α-pinene [*80-56-8*], which are added to liquid tetrafluoroethylene during purification and storage (at $-30\,°C$) [138]. In the United States, the transportation of liquid TFE containing stabilizers is permitted.

In the gas phase at ca. 300 – 500 °C, tetrafluoroethylene dimerizes to perfluorocyclobutane [139]. Above 600 °C, hexafluoropropylene (see Section 4.2) and the highly toxic perfluoroisobutene are formed [139].

Production. Many commercial processes for the production of tetrafluoroethylene are known, e.g., reaction of tetrafluoromethane in an electric arc [140], dechlorination of $CF_2Cl - CF_2Cl$ with a metal [141], and thermal decomposition of trifluoroacetic acid [142]:

$$2\,CF_3COOH \longrightarrow CF_2{=}CF_2 + 2\,HF + 2\,CO_2$$

The two principal commercial methods are pyrolysis of trifluoromethane [143]:

Table 12. Physical properties of fluoroolefins and chlorofluoroolefins

Property	Tetrafluoro-ethylene [*116-14-3*]	Hexafluoro-propene [*116-15-4*]	1,1-Difluoro-ethylene [*75-38-7*]	Fluoro-ethylene [*75-02-5*]	Chlorotri-fluoroethylene [*359-29-5*]	3,3,3-Tri-fluoro-prop-1-ene [*677-21-4*]

$$2\,CHF_3 \xrightarrow{700-800\,^\circ C} CF_2{=}CF_2 + 2\,HF$$

and pyrolysis of chlorodifluoromethane [144]:

$$2\,CHClF_2 \xrightarrow{600-800\,^\circ C} CF_2{=}CF_2 + 2\,HCl$$

In the second method (Fig. 2), the chlorodifluoromethane gas is passed at atmospheric or reduced pressure through a heated platinum, silver, or carbon tubular reactor (a). The 28 % conversion obtained under these conditions is low (yield, 83 %), but can be increased to ca. 65 % with the same yield by adding steam [145]. In modification of this method, chlorodifluoromethane is treated with superheated steam at ca. 700 °C, which results in a conversion rate of 60 – 80 % and a selectivity of 84 – 93 % [146]. The pyrolysis gas is washed with water (b) to cool it and to remove HCl. After being washed with caustic soda (c) and dried with concentrated sulfuric acid (d), the crude product can be stored in liquid or gaseous form (e). It is a complex mixture from which tetrafluoroethylene is separated by distillation in the presence of dipentene or a similar stabilizer to prevent polymerization. An overhead fraction containing inert gases and trifluoromethane is obtained in a low-boiling fractionation column (f) before isolating pure TFE (column g).

The higher-boiling fractions are processed (i) to recover unreacted $CHCl_2F$ and to isolate hexafluoropropene, a byproduct. Extractants such as methanol are added because of the formation of azeotropes during distillation [147]. Methanol also reacts with the toxic perfluoroisobutene, $(CF_3)_2C{=}CF_2$, to give an addition product.

Uses. Currently, tetrafluoroethylene is the most important fluoroolefin; it is used mainly for the production of fluoropolymers (→ Fluoropolymers, Organic). It reacts with perfluoronitrosoalkanes to produce so-called nitroso rubbers [148]. Tetrafluoroethylene is also used in the production of low molecular mass compounds and intermediates, e.g., for the manufacture of iodoperfluoroalkanes (see Section 3.4).

Polytetrafluoroethylene [*9002-84-0*], (PTFE) is a homopolymer sold under the trade names Algoflon (Montefluos), Fluon (ICI), Halon (Allied Chemical), Hostaflon TFE (Hoechst), Teflon PTFE (DuPont), Fluon (Asahi Glass), and Polyflon TFE (Daikin). Copolymers with fluorinated or fluorine-free olefins or vinyl ethers are also commercially available.

4.2. Hexafluoropropene

Properties. Hexafluoropropene (HFP), $CF_3CF{=}CF_2$, a colorless, odorless gas, is nonflammable in air at room temperature. For physical properties, see Table 12. It exhibits no special tendency toward radical homopolymerization [149], but like other fluoroolefins, it reacts readily with nucleophiles [128], [129].

Figure 2. Flow sheet for tetrafluoroethylene production
a) Pyrolysis reactor; b) Quench column (water); c) Wash column (NaOH); d) Drier (conc. H_2SO_4); e) Intermediate storage tank for crude tetrafluoroethylene; f) Fractionation column for low-boiling constituents; g) Product distillation column; h) Tetrafluoroethylene storage tank; i) Fractionation column

Liquid hexafluoropropene has unlimited storage life under pressure at room temperature in steel containers, even without stabilizers. In many countries the liquid can be transported in steel cylinders or tank cars. Hexafluoropropene is toxic (LC_{50} 3000 ppm) and can decompose thermally to form highly toxic perfluoroisobutene.

Production. Hexafluoropropene is produced commercially by temperature-controlled pyrolysis of chlorodifluoromethane (cf. production of tetrafluoroethylene, see Section 4.1) [150]. Hexafluoropropene can also be obtained from tetrafluoroethylene by heating at normal or reduced pressure, preferably in the presence of an inert gas (e.g., CO_2) or water vapor [151]:

$$3\,CF_2{=}CF_2 \xrightarrow{700-900\,^\circ C} 2\,CF_3CF{=}CF_2$$

Uses. An important application of hexafluoropropene is the production of copolymers, e.g., with tetrafluoroethylene or 1,1-difluoroethylene (→ Fluoropolymers, Organic, Chap. 2.3., → Fluoropolymers, Organic, Chap. 3.2.). The versatile epoxide, hexafluoropropylene oxide [*428-59-1*] (see Section 6.1.2), can be obtained from hexafluoropropene by oxidation.

4.3. 1,1-Difluoroethylene

vinylidene fluoride (VDF) $CH_2{=}CF_2$, is a commercially important, partially fluorinated olefin. It is a colorless, flammable gas that undergoes homopolymerization and copolymerization. For physical properties, see Table 12.

Production. Currently, three basic methods are used for the commercial production of vinylidene fluoride:

1) Dechlorination of 1,2-dichloro-1,1-difluoroethane [*1649-08-7*], R 132 b in the gas phase and on a metal catalyst [142], [152]:

$$CH_2ClCClF_2 \xrightarrow[Ni]{500\,^\circ C} CH_2{=}CF_2 + Cl_2$$

2) Dehydrochlorination of 1-chloro-1,1-difluoroethane [*75-68-3*], R 142 b [144], [153]:

$$CH_3CClF_2 \xrightarrow{700-900\,^\circ C} CH_2{=}CF_2 + HCl$$

In the presence of steam the temperature can be reduced to 500 – 650 °C [154].

3) Dehydrofluorination of 1,1,1-trifluoroethane [*420-46-2*], R 143 a [155]:

$$CH_3CF_3 \xrightarrow{1100-1300\,^\circ C} CH_2{=}CF_2 + HF$$

Vinylidene fluoride is transported as a liquid in steel cylinders without stabilizers.

Uses. 1,1-Difluoroethylene is the starting material for the commercially important homopolymer poly(vinylidene fluoride) [*24937-79-9*], (PVDF) (→ Fluoropolymers, Organic, Chap. 2.8.).

Trade Names (PVDF). Kynar (Atochem USA), Florafon (Atochem), Solef (Solvay), Neoflon (Daikin), KF (Kureha Chem.), Vidar (Süddeutsche Kalkstickstoffwerke). Worldwide annual production (1988): 7.4×10^3 t.

The copolymer with hexafluoropropene [*116-15-4*] is marketed as Viton (DuPont) and Fluorel (3M).

4.4. Monofluoroethylene, Monofluoroethylene

vinyl fluoride (VF), $CH_2{=}CHF$, is a colorless, highly flammable gas; up to 0.2 % of polymerization inhibitors are added for stabilization during transport and storage. For physical properties, see Table 12.

Production. In the past, vinyl fluoride was produced by dehydrofluorination of 1,1-difluoroethane [*75-37-6*], obtained in two steps by addition of hydrogen fluoride to acetylene [24, p. 59 – 66], [156]:

$$CH{\equiv}CH + 2\,HF \longrightarrow CH_3CHF_2 \xrightarrow{Cat.} CH_2{=}CHF + HF$$

However, with mercury catalysts, vinyl fluoride can be produced directly from acetylene and hydrogen fluoride [24, p. 59 – 66], [157]:

$$CH{\equiv}CH + HF \xrightarrow{Hg\ Cat.} CH_2{=}CHF$$

The dehydrochlorination of 1-chloro-1-fluoroethane [*1615-75-4*], $CHClFCH_3$, and 1-chloro-2-fluoroethane [*762-50-5*], CH_2FCH_2Cl, are also utilized commercially [158].

Uses. The main use of monofluoroethylene is in the production of poly(vinyl fluoride) [*24981-14-4*] (PVF) (→ Fluoropolymers, Organic, Chap. 2.8., → Fluoropolymers, Organic, Chap. 2.9.).

Trade Names (PVF). Tedlar (DuPont), Dalbon (Diamond Shamrock, USA). Worldwide annual production (1988): 1.6×10^3 t

4.5. 3,3,3-Trifluoropropene

3,3,3-Trifluoropropene, $CF_3CH{=}CH_2$ (TFP), is produced almost exclusively by fluorination and dehalogenation of 1,1,1,3-tetrachloropropane [*1070-78-6*] (TCP), $CCl_3CH_2CH_2Cl$. With sodium fluoride at 400 – 475 °C, trifluoropropene is obtained in a single step, involving chlorine – fluorine exchange and dehydrochlorination [159]. Using hydrogen fluoride and oxygen, the reaction can be carried out at 300 °C over a chromium fluoride catalyst [160]. Liquid-phase fluorination of 1,1,1,3-tetrachloropropane with hydrogen fluoride in the presence of an antimony catalyst yields 1,1,1-trifluoro-3-chloropropane, $CF_3CH_2CH_2Cl$, which gives 3,3,3-trifluoropropene when treated with a base [161]. The conversion is effected in a single operation with a mixture of hydrogen fluoride and a tertiary amine [162].

$$\begin{tikzcd} CCl_3CH_2CH_2Cl \arrow[r] \arrow[rr, bend right] & CF_3CH_2CH_2Cl \arrow[r] & CF_3CH{=}CH_2 \end{tikzcd}$$

A multistep synthesis starts from vinylidene fluoride ($CF_2{=}CH_2$) [163].

Uses. The main use of trifluoropropene is in the production of fluorine-containing silicones used in hydraulic fluids [159], [164].

4.6. 3,3,3-Trifluoro-2-(trifluoromethyl)-prop-1-ene

3,3,3-Trifluoro-1-(trifluoromethyl)prop-1-ene [*382-10-5*], hexafluoroisobutene, (HFIB), $(CF_3)_2C{=}CH_2$, is a colorless, toxic gas (4-h LC_{50} 1700 ppm) with a *bp* of 14.1 °C at 101.3 kPa. A number of processes for its production have been described; the most important use hexafluoroacetone [165] or perfluoroisobutene [166] as the starting material.

$$(CF_3)_2{=}O + CH_2{=}C{=}O \longrightarrow (CF_3)_2C{-}O \atop H_2C{-}C{=}O$$

$$\longrightarrow (CF_3)_2C{=}CH_2 + CO_2$$

$$(CF_3)_2C{=}CF_2 + CH_3OH \longrightarrow (CF_3)_2CHCF_2OCH_3$$

$$\xrightarrow[\text{steps}]{\text{Several}} (CF_3)_2C{=}CH_2$$

Acetic anhydride can be used with hexafluoroacetone instead of ketene. The multistep reaction takes place in a single operation in a copper reactor above 300 °C [167]. Presumably, processes based on the highly toxic perfluoroisobutene are designed to remove it as a harmful byproduct of tetrafluoroethylene or hexafluoropropene production.

Hexafluoroisobutene is used for the production of fluoropolymers. The trade name of the copolymer [*34149-71-8*] with vinylidene fluoride is CM-X (Ausimont) [168].

4.7. Chlorofluoroolefins

Among the numerous known chlorofluoroolefins [133], [134], 1,1-dichloro-2,2-difluoroethylene [*79-35-6*] has some importance as a starting material in the production of methoxyflurane [*76-38-0*], an inhalation anesthetic. However, chlorotrifluoroethylene is the most important member of this class.

Chlorotrifluoroethylene [*359-29-5*] (CTFE), $CF_2{=}CFCl$, a colorless, flammable gas, is less reactive than tetrafluoroethylene. For physical properties, see Table 12. Although chlorotrifluoroethylene is more stable than tetrafluoroethylene, stabilizers such as tributylamine are used during transportation and storage in steel cylinders [169]. Chlorotrifluoroethylene is toxic.

Production. Chlorotrifluoroethylene is produced commercially by dechlorination of 1,1,2-trichloro-1,2,2-trifluoroethane [*76-13-1*], (R 113) with zinc in methanol [170]:

$$CClF_2CCl_2F + Zn \xrightarrow{CH_3OH} CF_2{=}CClF + ZnCl_2$$

An alternative route is dechlorination in the gas phase, e.g., on an aluminum fluoride – nickel phosphate catalyst; this catalyst is highly stable [171].

Uses. Chlorotrifluoroethylene is a starting material for homopolymers and copolymers (PCTFE) (→ Fluoropolymers, Organic, Chap. 2.6., → Fluoropolymers, Organic, Chap. 2.7.). In addition, chlorotrifluoroethylene is an intermediate in the production of the inhalation anesthetic halothane. (2-Chloro-1,1,2-trifluoroethyl)-diethylamine [*357-83-5*], $ClFHCCF_2N(C_2H_5)_2$ (an addition product of chlorotrifluoroethylene with diethylamine), is used as a fluorinating agent to replace hydroxyl groups in steroids and carbohydrates with fluorine [54], [172]. Another use of chlorotrifluoroethylene is in telomerization with carbon tetrachloride or chloroform. The products are stabilized with fluorine or CoF_3 and are used as inert fluids, hydraulic fluids, or lubricants [104], [173].

Trade Names (PCTFE). Aclon (Allied-Signal), Daiflon (Daikin), Kel-F (3M), Voltalef (Atochem). Worldwide annual production (1988): 10^3 t.

5. Fluorinated Alcohols [174]

Primary and secondary alcohols that have fluorine and hydroxyl groups on the same carbon atom are unstable, and readily lose hydrogen fluoride to form carbonyl compounds. Primary and secondary perfluoroalkoxides, however, can be prepared in polar solvents under aprotic conditions from carbonyl compounds and a source of ionic fluoride [175]; typical counterions are alkali-metal, tetraalkylammonium, or tris(dialkylamino)sulfonium cations. The perfluoroalkoxides are moderately nucleophilic and are used in situ to prepare compounds containing perfluoroalkoxy groups (see Section 6.3).

Tris(dialkylamino)sulfonium perfluoroalkoxides are unusually stable and, in some cases, have been isolated as crystalline solids [176]. Tertiary perfluoro alcohols, e.g., perfluoro-*tert*-butanol (1,1,1,3,3,3-hexafluoro-2-trifluoromethyl-2-propanol) [*2378-02-1*] [177] and alcohols containing CH_2 groups between the fluorinated segment and the OH group are also stable. Fluorinated alcohols are more acidic than their nonfluorinated analogues because fluorine is highly electronegative (see Table 13) [178].

Table 13. pK_a values of alcohols [178]

Alcohol	R = H	R = F
CR_3CH_2OH	15.9	12.8
$(CR_3)_2CHOH$	17.1	9.3
$(CR_3)_3COH$	19.2	5.4

Short-Chain Fluoroalcohols. Of the short-chain fluorinated alcohols (C_2–C_4), only 2,2,2-trifluoroethanol [*75-89-8*], *bp* 73.6 °C, and 1,1,1,3,3,3-hexafluoro-2-propanol [*920-66-1*], *bp* 58.2 °C, have achieved commercial importance. The former is prepared by catalytic hydrogenation of trifluoroacetamide [179], trifluoroacetyl chloride [180], or trifluoroacetic acid esters [181], or by reduction of trifluoroacetic acid with metal hydrides [182]. Similar processes are used to prepare the latter from hexafluoroacetone [183]. Because of their strong tendency to form hydrogen bonds, the fluorinated alcohols form stable complexes with hydrogen bond acceptors and are excellent solvents for polar polymers [184]. Ethers derived from these alcohols are used as inhalation anesthetics (see Section 6.3). 2-Aryl-1,1,1,3,3,3-hexafluoro-2-propanols are prepared by alkylation of aromatic compounds with hexafluoroacetone [185]. Tertiary diols, e.g., 1,3-bis(2-hydroxyhexafluoro-2-propyl) benzene [*802-93-7*] are used to prepare fluoroepoxy resins [186].

Long-Chain Fluoroalcohols. The unique hydro- and oleophobic properties of long perfluoroalkyl chains lead to many applications of long-chain fluoroalcohols and their derivatives as surfactants, antisoilants, and surface-treatment agents [187]. Structures can be represented by,

$$X-(CF_2)_n(CH_2)_mOH$$

where X is typically F, H, or CH_3, n is 6–12, and m is 1 or 2. The most important compounds are the 1*H*,1*H*-perfluoroalcohols (X = F, $m = 1$), prepared by reduction of the corresponding perfluorinated carboxylic acids [188], and the 1*H*,1*H*,2*H*,2*H*-perfluoroalcohols (X = F, $m = 2$); the latter are prepared by treatment of the corresponding 1-iodo-1*H*,1*H*,2*H*,2*H*-perfluoroalkanes with oleum [189]. Alcohols of the formula $H(CF_2)_nCH_2OH$, where n is an even number, are prepared by telomerization of tetrafluoroethylene with methanol [190].

For use as soil-repellent finishes, the long-chain fluoroalcohols are converted into derivatives to adjust the hydrophobicity, solubility in aqueous and organic solutions, surface retention, and stability for each specific application. These derivatives include esters, phosphates, carboxylates, and polyoxyethylenes. Polymeric alcohols are prepared by esterification with (meth)acryloyl chloride, followed by polymerization.

Trade Names. Teflon, Zepel, and Zonyl (DuPont), Scotchgard (3M), and Oleophobal (Chemische Fabrik Pfersee, Ciba-Geigy).

6. Fluorinated Ethers [191]

6.1. Perfluoroethers

Perfluorinated ethers are less basic than their hydrogen-containing analogues [192]. The saturated aliphatic and cycloaliphatic perfluoroethers are noncombustible, and, with the exception of the perfluorinated epoxides, display high chemical and thermal stability. Other properties of the stable ethers, such as a large difference between the melting and boiling points at ambient pressure, and a low pour point, surface tension, and dielectric constant, are the basis of applications such as dielectric and heat-exchange fluids in, for example, high power transformers. Higher molecular mass perfluoroethers are used as lubricants and hydraulic flu-

ids in extreme service conditions, i.e., at high temperature and/or in a corrosive environment.

6.1.1. Low Molecular Mass Perfluoroethers

The low molecular mass perfluoroethers are usually prepared by electrochemical fluorination of aliphatic ethers, alcohols, or carboxylic acids [193]. Typical empirical formulas are $C_6F_{12}O$, $C_7F_{14}O$, and $C_8F_{16}O$; these ethers often consist of isomer mixtures. Compound FC-75 [*11072-16-5*] (3M), mostly perfluorobutyltetrahydrofurans, is a useful solvent that has been explored as an oxygen-transport agent in artificial blood [194]. Perfluorinated ethers can also be prepared from partially fluorinated or nonfluorinated ethers by fluorination with cobalt fluoride or elemental fluorine under carefully controlled conditions [195].

Trade Names. Fluorinert liquids (3M) and Galden fluorinated fluids (Montedison).

6.1.2. Perfluorinated Epoxides

In contrast to other perfluorinated cyclic ethers, ring strain in perfluorinated epoxides results in high reactivity, making them versatile precursors to other fluorinated compounds [196]. The most important is hexafluoropropylene oxide [*428-59-1*] (HFPO), trifluoro(trifluoromethyl)oxirane [197]. It is prepared from hexafluoropropene by reaction with elemental oxygen [198], by electrochemical oxidation [199], or by reaction with hypochlorites [200] or hydrogen peroxide [201] in alkaline media.

Hexafluoropropylene oxide (*bp* $-27.4\,^{\circ}C$) is stable at room temperature, but decomposes above 150 °C to form trifluoroacetyl fluoride and difluorocarbene [202]. In the presence of strong Brønsted or Lewis acids, such as alumina or aluminum chloride, HFPO undergoes catalytic rearrangement to hexafluoroacetone, constituting a convenient synthesis of this compound [203]. Most significantly, HFPO reacts readily with nucleophiles. Attack usually occurs at the central carbon atom [204], resulting in formation of an acid fluoride by loss of a fluoride ion from the intermediate perfluoroalkoxide, which can react further with HFPO to form higher oligomers. Acid fluorides are precursors to the commercially important perfluorovinyl ethers and higher molecular mass perfluoroethers.

where X = nucleophile, e.g., fluoride ion.

Both tetrafluoroethylene oxide [*694-17-7*] (TFEO), also called tetrafluorooxirane [205], and epoxides of longer chain-length perfluoroolefins [206] are known; however, the former is unstable at room temperature and rearranges to form trifluoroacetyl fluoride, whereas the latter are prepared from inaccessible perfluoroolefins. Only HFPO has achieved commercial significance because it is used for the synthesis of hexafluoroacetone (see page 27), high molecular mass perfluoroethers, Section 6.1.3, and fluorinated vinyl ethers (Section 6.2).

6.1.3. High Molecular Mass Perfluoroethers

High molecular mass perfluorinated ethers are prepared by fluoride-catalyzed oligomerization of HFPO [207]. The resulting terminal acid fluoride group is removed by hydrolysis and decarboxylative fluorination with elemental fluorine. Chemically inert ethers are produced which have the formula,

These ethers are obtained in various molecular mass and viscosity ranges by controlling oligomerization conditions or by partial distillation of the oligomeric mixture. In an alternative method [208], perfluorinated olefins (e.g., tetrafluoroethylene or hexafluoropropene) react photochemically with oxygen to form oligomeric perfluoroethers with terminal acid fluoride groups and peroxide bonds [209]. These end groups and the unstable peroxide linkages are eliminated by fluorination. Perfluoroethers with molecular masses of ca. 500 – 6000 are used as inert fluids, lubricants, and hydraulic fluids in

applications that require resistance to high temperature or strongly corrosive environments.

Trade Names. Krytox (DuPont), Aflunox (SCM Specialty Chemicals), and Fomblin (Montedison).

6.2. Perfluorovinyl Ethers

Perfluorovinyl ethers are comonomers used in the preparation of melt-processable perfluoroplastics, fluorinated elastomers, and perfluoropolymers containing functional groups [210] (→ Fluoropolymers, Organic, Chap. 3.3.). The ethers are synthesized by reaction of a fluorinated alkoxide generated in situ, or of other nucleophiles with HFPO. The resulting acid fluorides are converted to acid salts, which lose carbon dioxide and metal fluoride when heated in an aprotic environment. For example, HFPO is treated with cesium trifluoromethoxide (from cesium fluoride and carbonyl fluoride). Hydrolysis and decarboxylation of the resulting acid fluoride gives perfluoro(methyl vinyl ether) [*1187-93-5*].

$$CF_2O + CsF \longrightarrow CF_3OCs \xrightarrow{\text{HFPO}}$$

$$CF_3OC(CF_3)COF \xrightarrow[\text{2) heat}]{\text{1) } H_2O} CF_3OCF{=}CF_2$$

This compound is a comonomer with tetrafluoroethylene in a perfluorinated elastomer [211].

Perfluoro(propyl vinyl ether) [*1623-05-8*], $CF_3CF_2CF_2OCF{=}CF_2$, prepared from the dimer of HFPO [212], is copolymerized with tetrafluoroethylene to a melt-processable perfluoroplastic.

Perfluorovinyl ethers containing specific functional groups and usually two or more moles of hexafluoropropylene oxide are prepared in a similar fashion. These compounds have the structure $RO(C_3F_6O)CF{=}CF_2$; they are used as functional groups in perfluoroelastomers which can undergo a crosslinking reaction, i.e., cure-site monomers ($R = CF_2CF_2CN$ or pentafluorophenyl) [213] and as monomers that provide the ionic groups in perfluorinated ion-exchange resins ($R = CF_2CF_2SO_2F$, $CF_2CF_2CF_2CO_2CH_3$, or $CF_2CF_2CO_2CH_3$) [214]. Synthesis of the sulfonyl fluoride-substituted vinyl ether is illustrative. Reaction of tetrafluoroethylene with sulfur trioxide gives a sultone, which rearranges to fluorosulfonyldifluoroacetyl fluoride. The anion formed after addition of fluoride ion to this acid fluoride gives a 2 : 1 adduct with HFPO [215]. Pyrolysis of the sodium salt over sodium carbonate gives the functional monomer [216].

$$CF_2{=}CF_2 + SO_3 \longrightarrow \underset{O}{CF_2}-\underset{SO_2}{CF_2} \longrightarrow FO_2SCF_2COF$$

$$FO_2SCF_2CFO + 2\,CH_3C(O)F-CF_2 \xrightarrow{F^-}$$

$$FO_2SCF_2CF_2OC(CF_3)CF_2OC(CF_3)FO \xrightarrow[\text{heat}]{Na_2CO_3}$$

$$FO_2SCF_2CF_2OC(CF_3)CF_2OCF{=}CF_2$$

Perfluorovinyl ethers can also be prepared by deiodofluorination of iodine-containing ethers, $XR_fCF_2OCF_2CF_2I$, where X is hydrogen, halogen, CO_2R, $CONR_2$, SO_2F, or $PO(OR)_2$ (R = alkyl) and R_f is a perfluoroalkyl group. Initially, an organometallic derivative of the iodide is formed by reaction with metals, such as Mg, Cu, Zn, Sn, or Sb. Heating in the absence of a proton source affords the vinyl ethers [217].

6.3. Partially Fluorinated Ethers

Partially fluorinated ethers are synthesized by several methods. Fluoroalkyl alkyl or fluoroalkyl aryl ethers are prepared from alkoxides or phenoxides and fluoroolefins [218]; for example, 1,1,2,2-tetrafluoro-1-methoxyethane [*425-88-7*] is prepared from tetrafluoroethylene and sodium methoxide – methanol. Higher perfluoroolefins can also be employed [219]. The methyl ethers are valuable intermediates, which can be converted to acid fluorides with sulfur trioxide [220] or other Lewis acids [221]. Primary and secondary perfluorinated alkoxides (see Chap. 5) are not sufficiently nucleophilic to react with fluorinated or nonfluorinated olefins. However, they react with a variety of olefins in the presence of halogen to give ethers [222], e.g.,

$$(CF_3)_2CFO^- + CH_2{=}CF_2 + ICl \longrightarrow (CF_3)_2CFOCF_2CH_2I + Cl^-$$

Perfluoroalkoxides react with benzyl halides to give perfluoroalkyl benzyl ethers [223].

In contrast to the physiological inertness of perfluoroethers, some partially fluorinated ethers act as inhalation anesthetics. Many cyclic and acyclic ethers containing varying amounts of fluorine, hydrogen, and sometimes other halogens have been evaluated as anesthetics in search of the ideal combination of potency, volatility, lack of short- and long-term toxicity, and nonflammability [224]. Some ethers have achieved clinical significance (→ Anesthetics, General, Chap. 2.5.).

The first fluorinated ether anesthetic to be introduced clinically was2,2,2-trifluoro-1-vinyloxyethane [*406-90-6*] [trade name: Fluromar (Anaquest)] [225]. It is prepared by addition of 2 mol of trifluoroethanol to acetylene, followed by thermolysis:

$$2\,CF_3CH_2OH + HC{\equiv}CH \longrightarrow CH_3CH(OCH_2CF_3)_2 \longrightarrow CH_2{=}CHOCH_2CF_3$$

The flammability behavior of the compound is not significantly better than that of nonfluorinated anesthetics, and it behaves as a mutagen in the Ames test [226]; therefore, the compound is not currently produced commercially.

2-Chloro-1-(difluoromethoxy)-1,1,2-trifluoroethane [*13838-16-9*] [trade name: Ethrane (Anaquest)], which is nonflammable, is prepared by successive chlorination and fluorination of the hydrocarbon ether [227]. 1-Chloro-1-(difluoromethoxy)-2,2,2-trifluoroethane [*26675-46-7*] [trade name: Forane (Anaquest)] is prepared in a similar fashion [228]. Other possible anesthetics include 2,2-dichloro-1,1-difluoro-1-methoxyethane [*76-38-0*] [229] and 1,1,1,3,3,3-hexafluoro-2-(fluoromethoxy)propane [*28523-86-6*] [230].

7. Fluorinated Ketones and Aldehydes

The carbonyl groups in partially or perfluorinated ketones and aldehydes are electron deficient owing to the inductive effect of the highly electronegative fluorine atom. Compared with their hydrocarbon counterparts, fluorinated ketones and aldehydes are, consequently, much more reactive toward nucleophilic reagents. Stable addition compounds with water, alcohols, and amines are commonly formed. By contrast, fluorinated ketones and aldehydes are relatively unreactive toward electrophilic reagents. An extreme case is hexafluoroacetone, which is not protonated by the FSO_3H-SbF_5 superacid [231].

A wide variety of fluoroalkyl ketones and aldehydes has been synthesized, often by special methods that are unique to polyfluorinated compounds [232]. Of the many known examples, a few fluorinated acetones, aldehydes, and 1,3-diketones are of practical importance.

7.1. Fluoro- and Chlorofluoroacetones

Several fluoro- and chlorofluoroacetones (propanones) are listed in Table 14. Hexafluoroacetone and, to a lesser extent, chloropentafluoroacetone and *sym*-dichlorotetrafluoroacetone are commercially important. Hexafluoroacetone is manufactured by DuPont in the United States and by Hoechst in the Federal Republic of Germany. The two chlorofluoroacetones were made in pilot-plant quantities by Allied in the 1960s [233], but their production has been discontinued.

Hexafluoroacetone, 1,1,1,3,3,3-hexafluoro-2-propanone, is made industrially by the vapor-phase reaction of hexachloroacetone with hydrogen fluoride in the presence of a chromium catalyst [234], [235]. The rearrangement of hexafluoropropylene oxide induced by Lewis acids [203] is an attractive new route that avoids the highly toxic *sym*-dichlorotetrafluoro- and chloropentafluoroacetones. A convenient laboratory synthesis uses hexafluoropropylene as a starting material [236]:

$$2\,CF_3CF{=}CF_2 + \tfrac{1}{4}S_8 \xrightarrow[\text{dimethylformamide}]{KF}$$

Table 14. Molecular masses and boiling points of fluoro- and chlorofluoropropanones

Name	CAS registry no.	Formula	M_r	*bp*, °C (101.3 kPa)
1,1,1-Trifluoro-2-propanone	[*421-50-1*]	CF_3COCH_3	112.05	21.5 – 22.5
1,1,3,3-Tetrafluoro-2-propanone	[*360-52-1*]	CHF_2COCHF_2	130.05	58
1,1,1,3,3,3-Hexafluoro-2-propanone	[*684-16-2*]	CF_3COCF_3	166.03	− 27.4
1-Chloro-1,1,3,3,3-pentafluoro-2-propanone	[*79-53-8*]	$CClF_2COCF_3$	182.48	7.8
1,3-Dichloro-1,1,3,3-tetrafluoro-2-propanone	[*127-21-9*]	$CClF_2COCClF_2$	198.93	45.2
1,1,3-Trichloro-1,3,3-trifluoro-2-propanone	[*79-52-7*]	$CCl_2FCOCClF_2$	215.38	84.5
1,1,3,3-Tetrachloro-1,3-difluoro-2-propanone	[*79-51-6*]	$CCl_2FCOCCl_2F$	231.83	123.9
1,1,1,3,3-Pentachloro-3-fluoro-2-propanone	[*2378-08-7*]	CCl_3COCCl_2F	248.28	163.7
1,1,1,3,3,3-Hexachloro-2-propanone	[*116-16-5*]	CCl_3COCCl_3	264.73	203.6

Hexafluoroacetone is used mainly for the manufacture of the solvent hexafluoro-2-propanol and high-performance fluoropolymers. For the properties, chemistry, and uses of hexafluoroacetone, see Acetone, Chap. 11.3..

Chloropentafluoroacetone, 1-chloro-1,1,3,3,3-pentafluoro-2-propanone [trade name: 5FK (Allied)] and *sym*-dichlorotetrafluoroacetone, 1,3-dichloro-1,1,3,3-tetrafluoro-2-propanone (4FK, Allied) can be made by the incomplete exchange of chlorine in hexachloroacetone, using hydrogen fluoride and a Cr^{3+} or Cr^{5+} catalyst [234], [235], [237]. Their properties and chemical reactivities are similar to those of hexafluoroacetone [238]. Like hexafluoroacetone, chloropentafluoroacetone and *sym*-dichlorotetrafluoroacetone form stable, acidic hydrates and hemiacetals, e.g., $CClF_2COCF_3 \cdot 3\,H_2O$ [*34202-28-3*], *bp* 105 °C, and $CClF_2COCClF_2 \cdot 2\,H_2O$ [*34202-29-4*], *bp* 106 °C. The hydrates are powerful solvents for acetal resins and various polar polymers [239], [240]. These chlorofluoroacetones and some of their derivatives possess herbicidal or fungicidal activity [241–243] and are useful intermediates for synthesizing repellants for textile fibers [244], [245], specialty polycarbonates [246], [247], and inhalation anesthetics [248].

1,1,1-Trifluoro-2-propanone can be prepared in quantitative yield by the acid hydrolysis of ethyl trifluoroacetoacetate, the ethyl ester of 4,4,4-trifluoro-3-oxobutanoic acid [*372-31-6*], which is made by the alkali-promoted condensation of ethyl trifluoroacetate with ethyl acetate [249]. 1,1,1-Trifluoro-2-propanone is easily made in the laboratory by the reaction of trifluoroacetic acid with methylmagnesium iodide [250]. Its aryl hydrazone derivatives show nematocidal and acaricidal activity [251].

1,1,3,3-Tetrafluoro-2-propanone is made by the acid hydrolysis of the ethyl ester of 2,2,4,4-tetrafluoro-3-oxobutanoic acid, $CHF_2COCF_2\ CO_2C_2H_5$ [249]. The ketone is used as an intermediate in the synthesis of inhalation anesthetics [252], [253].

7.2. Perhaloacetaldehydes

Perchlorfluoroacetaldehydes. Some physical properties of the *perchlorofluoroacetaldehydes* are shown in Table 15. Their chemical reactivities are similar to those of the perchlorofluoroacetones.

Chlorodifluoroacetaldehyde and dichlorofluoroacetaldehyde can be prepared by the lithium aluminum hydride reduction of the corresponding methyl chlorofluoroacetates [254], [255].

Trifluoroacetaldehyde (fluoral) and some of its derivatives have found practical importance as monomers and intermediates for biologically active compounds.

Properties. Trifluoroacetaldehyde is a colorless gas at ambient temperature and pressure. Like hexafluoroacetone, it reacts

Table 15. Molecular mass and boiling points of perchlorofluoroacetaldehydes

Name	Formula	M_r	CAS registry no.	*bp*, °C (101.3 kPa)
Trichloroacetaldehyde	CCl_3CHO	147.38	[*75-87-6*]	97.8
Dichlorofluoroacetaldehyde	CCl_2FCHO	130.93	[*63034-44-6*]	56
Chlorodifluoroacetaldehyde	$CClF_2CHO$	114.48	[*811-96-1*]	17.8
Trifluoroacetaldehyde	CF_3CHO	98.03	[*75-90-1*]	− 18 to − 19∗

∗ At 99.7 kPa

with water to form a stable, solid hydrate – 1,1-dihydroxy-2,2,2-trifluoroethane [*421-53-4*], $CF_3CH(OH)_2$, *mp* 69 – 70 °C. It reacts in a manner similar to hexafluoroacetone with alcohols to give stable hemiacetals: 2,2,2-trifluoro-1-methoxyethanol [*431-46-9*], $CF_3CH(OH)OCH_3$, *bp* 96 – 96.5 °C; and 2,2,2-trifluoro-1-ethoxyethanol [*433-27-2*], $CF_3CH(OH)OC_2H_5$, *bp* 104 – 105 °C (99.3 kPa). Unlike hexafluoroacetone, it readily homopolymerizes upon cationic, anionic, or free-radical initiation [254], [255].

Production. Several laboratory syntheses of trifluoroacetaldehyde have been developed, including reduction of trifluoroacetic acid and its alkyl esters, trifluoroacetic anhydride, and trifluoroacetyl chloride [256]. Trifluoroacetaldehyde can be manufactured on a large scale by the reaction of trichloroacetaldehyde (chloral) with hydrogen fluoride in the presence of chromium catalysts [235]. The product is a $CF_3CHO \cdot HF$ complex, *bp* 38 °C (133.3 kPa), which requires treatment with a hydrogen fluoride acceptor (e.g., sodium fluoride) to give free trifluoroacetaldehyde. Hydrolysis of the inhalation anesthetic Halothane, $CF_3CHBrCl$, by a mixture of 65 % oleum, mercuric oxide, and silver oxide also produces trifluoroacetaldehyde in high yield [257].

Trifluoroacetaldehyde is commercially available as its hydrate or methyl and ethyl hemiacetals, which liberate the pure aldehyde in polyphosphoric acid at 150 – 180 °C. A Hoechst process for the manufacture of its hemiacetals involves treating the product from the gas-phase fluorination of chloral with tetraalkoxyl silanes, or with alcohols and silicon tetrachloride. This process avoids the need to isolate or handle free trifluoroacetaldehyde [258], [259].

$$CCl_3CHO \xrightarrow[CrO_2F_2]{HF} CF_3CHO \cdot HF \xrightarrow{(RO)_4Si} CF_3CH(OH)OR$$

R = alkyl

Uses of Perhaloacetaldehydes. Certain oximes [260] and hydrazones [251] of trifluoroacetaldehyde have insecticidal or acaricidal activity. Its hemiacetal, 2,2,2-trifluoro-1-methoxyethanol, has been used as a starting material for the preparation of fluoroether inhalation anesthetics [261] (see Section 6.3), including isoflurane, $CF_3CHClOCHF_2$ [262], and its isomer $CF_3CHFOCHClF$ [263], [264].

The stereoregularity of perchlorofluoroacetaldehyde polymerizations has been an area of active research, although no commercial uses of the polymers have yet appeared.

Trifluoroacetaldehyde can be homopolymerized to give insoluble crystalline, or soluble, amorphous, polyoxymethylene polymers depending upon the polymerization conditions [254], [255]. This is in contrast with trichloroacetaldehyde which can only be polymerized to a crystalline, apparently isotactic polymer. Copolymers of perhaloacetaldehydes have been prepared [254], [255].

7.3. Fluorinated 1,3-Diketones

Fluorinated 1,3-diketones in which the two carbonyl groups are separated by a methylene or methine group form complexes with a wide variety of metal ions. This property is the basis of their utility in chromatographic analysis of metals, laser technology, NMR spectroscopy, and hydrometallurgical separations. The properties, preparation, and uses of fluorinated 1,3-diketones and theirmetal complexes have been extensively reviewed [265–267].

Properties and Production. Some physical properties of the industrially important fluorinated 1,3-diketones are shown in Table 16. These compounds are considerably more acidic than their nonfluorinated analogues, i.e., 1,3-pentanedione [*123-54-6*], $CH_3COCH_2COCH_3$ ($pK_a = 8.9$), $CF_3COCH_2COCH_3$ ($pK_a = 6.7$), and $CF_3COCH_2COCF_3$ ($pK_a = 4.6$) [267]. Fluorinated 1,3-diketones have a high enolic content, typically 92 – 100 %, in comparison with ca. 80 % for 1,3-pentanedione. Their enolic protons can be readily replaced by metals or metal salts to form 1,3-diketonates of the type

Fluorinated 1,3-diketones form hydrates with water and hemiketals with shorter alcohols. They are usually obtained by a Claisen condensation of a fluorinated carboxylic acid ester with a ketone, using a strong base such as a sodium alkoxide or sodium hydride.

Uses. The 1,3-diketones $RCOCH_2COR'$ ($R = CF_3$, n-C_3F_7 and $R' = t$-C_4H_9, CF_3) that form volatile, thermally and hydrolytically stable complexes are useful for liquid or gas chromatographic analysis of metals. These diketones, especially 1,1,1,2,2,3,3-heptafluoro-7,7-dimethyl-4,6-octanedione are widely used for the extraction of metal ions from aqueous solutions at variable pH [268].

4,4,4-Trifluoromethyl- 1-(2-thienyl)-1,3-butanedione is especially suited for the analysis of uranium and other radioactive elements. The *tetrakis*-chelates of 4,4,4-trifluoro-1-phenyl-1,3-butanedione with rare-earth elements are potential laser materials.

The paramagnetic lanthanide complexes of heptafluoro-7,7-dimethyl-4,6-octanedione have gained considerable importance as NMR shift reagents for simplifying the interpretation of complex NMR spectra [269]; the europium complex is the most widely used.

M = Ag; $n = 1$
M = Dy, Eu, Gd, Ho, Pr, Yb; $n = 3$

The chiral-shift reagents derived from 3-heptafluorobutyryl-(+)- or -(−)-camphor and 3-trifluoroacetyl-(+)- or -(−)-camphor are very useful for the NMR assay of enantiomeric purity in solution [269].

R = CF_3, n-C_3F_7
M = Eu, Pr, Yb

8. Fluorinated Carboxylic Acids and Fluorinated Alkanesulfonic Acids

8.1. Fluorinated Carboxylic Acids

8.1.1. FluorinatedAcetic Acids

Fluorination increases the strength of acetic acid as seen in the pK_a values of monofluoroacetic acid (2.66), difluoroacetic acid (1.24), and trifluoroacetic acid (0.23) compared to the pK_a of 4.74 for acetic acid [270].

Production. Trifluoroacetic acid has been prepared by the electrochemical fluorination of acetyl chloride or acetic anhydride in anhydrous hydrogen fluoride using the Simons process (Section 2.1) followed by hydrolysis of the resulting trifluoroacetyl fluoride. The yield is excellent (> 90 %) [271], [272]. The Phillips Petroleum electrochemical process (Section 2.1) employs acetyl fluoride as feed to produce trifluoroacetyl fluoride along with mono and difluoroacetyl fluoride [273]. Sulfur trioxide treatment of CF_3CCl_3, obtained by isomerization of Freon 113, $CF_2ClCFCl_2$, yields CF_3COCl [274]. The acid is purified by hydrolysis of the acyl halide with alkali, followed by acidification and distillation.

Uses. Most uses of fluorinated acetic acids are confined to trifluoroacetic acid, its anhydride, and its derivative, 1,1,1-trifluoroethanol.

Table 16. Molecular masses and boiling points of fluorinated 1,3-diketones

Name	CAS registry no.	Formula	M_r	*bp*, °C (kPa)
1,1,1-Trifluoro-2,4-pentanedione	[*367-57-7*]	$CF_3COCH_2COCH_3$	154.09	105 – 107 (101.3)
1,1,1,5,5,5-Hexafluoro-2,4-pentanedione	[*1522-22-1*]	$CF_3COCH_2COCF_3$	208.06	70 – 71 (101.3)
1,1,1-Trifluoro-5,5-dimethyl-2,4-hexanedione	[*22767-90-4*]	$CF_3COCH_2COC(CH_3)_3$	196.17	138 – 141 (101.3)
1,1,1,2,2,3,3-Heptafluoro-7,7-dimethyl-4,6-octanedione	[*17587-22-3*]	$CF_3CF_2CF_2COCH_2COC(CH_3)_3$	296.19	46 – 47 (0.67)

3-(Heptafluorobutyryl)camphor, 3-(2,2,3,3,4,4,4-heptafluoro-1-oxo-butyl)-bicyclo[2.2.1]heptan-2-one	[*51800-99-8*]		348.26	60 – 70 (0.03)

[a] *mp* 38 – 40 °C. [b] *mp* 42 – 43 °C.

Monofluoroacetic acid derivatives (salts, esters, amides, and alcohols) are toxic because they are metabolized to fluorocitric acid which inhibits respiration (see Section 13.5) [275]. ω-Fluoro acids of the formula $F(CH_2)_nCOOH$, where n is an odd number, are extremely toxic, because of degradation in vivo to monofluoroacetic acid and finally to fluorocitric acid [275]. Sodium monofluoroacetate has been used as a rodenticide, but is now banned.

8.1.2. Long-Chain Perfluorocarboxylic Acids

Properties. The boiling points and densities of straight-chain perfluorocarboxylic acids are shown in Table 17.

Production. Long-chain perfluorocarboxylic acids are prepared by the Simons electrochemical fluorination (see Section 2.1.) of the corresponding acyl halide:

Table 17. Boiling points and densities of perfluorocarboxylic acids

Acid	CAS registry no.	Formula	*bp*, °C (kPa)	d_4^{20}, g/cm^3
Perfluoroacetic	[*76-05-1*]	CF_3CO_2H	72.4	1.489
Perfluoropropionic	[*422-64-0*]	$C_2F_5CO_2H$	96	1.561
Perfluorobutyric	[*375-22-4*]	$C_3F_7CO_2H$	120	1.651
Perfluorovaleric	[*2706-90-3*]	$C_4F_9CO_2H$	130	
Perfluorocaproic	[*307-24-4*]	$C_5F_{11}CO_2H$	157	1.762
Perfluoroheptanoic	[*375-85-9*]	$C_6F_{13}CO_2H$	175	1.792
Perfluorocaprylic	[*335-67-1*]	$C_7F_{15}CO_2H$	189	
Perfluorononanoic	[*375-95-1*]	$C_8F_{17}CO_2H$	110 (2.1)	
Perfluorocapric	[*335-76-2*]	$C_9F_{19}CO_2H$	121 (2.0	
Perfluoroundecanoic	[*2058-94-8*]	$C_{10}F_{21}CO_2H$	245	
Perfluorododecanoic	[*307-55-1*]	$C_{11}F_{23}CO_2H$	270	

$$C_nH_{2n+1}COF + (2n+1)\,HF \longrightarrow C_nF_{2n+1}COF + (2n+1)H_2$$

The acids are obtained by hydrolysis of the perfluoroacyl fluoride, followed by distillation. Some carbon–carbon bond scission occurs to form lower homologous acids along with inert fluorocarbons and cyclic ethers. The acid yield decreases with increasing chain length; for example, perfluorobutyric acid yields are ca. 36 % compared to ca. 20 % for the industrially important perfluorooctanoic acid [271], [272]. Trifluoroacetic acid is also prepared by the Phillips electrochemical method, employing a $KF \cdot HF$ molten salt electrolyte [273]. Acids with higher boiling points are not easily or efficiently prepared by the Phillips process.

Perfluorocarboxylic acids are also prepared by nonelectrochemical methods. Treatment of perfluoroalkyl iodides (R_fI) with sulfur trioxide [276] or chlorosulfonic acid [277] gives the carboxylic acid in good yield. Another method employs fuming sulfuric acid (oleum) [278]. Another process involves the preparation of perfluorotetrahydroalkyl iodides, $R_fCH_2CH_2I$, obtained by the free-radical addition of ethylene to perfluoroalkyl iodides, followed by dehydroiodination and oxidation by dichromate [279] or ozonolysis [280]:

$$C_nF_{2n+1}I + CH_2{=}CH_2 \longrightarrow C_nF_{2n+1}CH_2CH_2I \xrightarrow{-HI}$$
$$C_nF_{2n+1}CH{=}CH_2 \xrightarrow[\text{or } O_3]{Cr_2O_7^{2-}} C_nF_{2n+1}COOH$$

This process produces carboxylic acids having one more carbon atom than the starting perfluoroalkyl iodide, in contrast to the electrochemical and oleum routes, which produce acids containing the same number of carbon atoms as the original acyl halide or telomeric iodide. In all processes utilizing fluorinated iodine-containing telomers, it is important to find uses for the telomers and to recover the expensive iodine.

Polyfluoroalkoxyacyl fluorides of the type

$$R_fCF_2O(\overset{\overset{\displaystyle CF_3}{|}}{C}FCF_2O)_nCF\overset{\overset{\displaystyle CF_3}{|}}{C}FO$$

are prepared by the addition of perfluoroacyl fluorides and hexafluoropropylene oxide catalyzed by alkali-metal fluorides [281]. Acids, salts, or esters are obtained by hydrolysis, neutralization, or esterification, respectively.

Addition reactions of perfluorodiacyl fluorides with hexafluoropropylene oxide [282] give ether-containing diacyl fluorides, such as

$$FCO\overset{\overset{\displaystyle CF_3}{|}}{C}FO(CF_2)_nO(\overset{\overset{\displaystyle CF_3}{|}}{C}FCF_2O)_m\overset{\overset{\displaystyle CF_3}{|}}{C}FCOF$$

where n is usually 2 – 4, and at least two units are derived from hexafluoropropylene oxide (i.e., $m \geq 2$) [282]. The addition reaction may occur at one or both acyl groups of the starting diacyl fluoride. Selectivity can be maintained by esterifying one of the acyl fluoride groups. Thus, $CH_3OCO(CF_2)_2COF$, prepared by addition of methanol to perfluoro-γ-butyrolactone or perfluorosuccinyl fluoride, reacts with hexafluoropropylene oxide to give ester acyl fluorides of the formula

[283], [284]. The acyl halides are converted to acids or salts by hydrolysis or neutralization, respectively.

Uses. Long-chain perfluoroalkanecarboxylic acids and their salts are surface-active chemicals (surfactants), which greatly reduce the surface tension (surface energy) of water, aqueous solutions, and organic liquids even at low concentrations. These acids (C_6–C_{12}) and derivatives are used as wetting, dispersing, emulsifying, and foaming agents.

Ammonium perfluorooctanoate (FC-143, 3M) is used as an emulsifier in the polymerization of fluorinated monomers, especially tetrafluoroethylene. It has exceptional chemical stability and lowers the surface tension of water to ca. 3 μN · m at 0.5 wt %. In contrast with hydrocarbon emulsifiers, ammonium perfluorooctanoate does not interfere with the emulsion polymerization of tetrafluoroethylene.

Trade Names. Fluorad FC-26, 126, 143 (3M), Fluorowet CP (Hoechst), RM 350, 370 (Rimar), and Surflon S-111P (Asahi Glass).

8.1.3. Fluorinated Dicarboxylic Acids

Properties. The boiling points and densities of perfluorodicarboxylic acids are shown in Table 18.

Production. α,ω-Perfluoroalkanedicarboxylic acids are prepared by the electrochemical method, followed by hydrolysis, acidification, and extraction. Other methods include the oxidation of the appropriate chlorofluoroolefin or perfluoroolefin. Perfluoroglutaric acid is prepared from hexachlorocyclopentadiene by halogen exchange, followed by oxidation and acidification [285]. Perfluoroadipic acid is prepared by an analogous method from hexachlorobenzene [286]. The cyclic anhydrides from perfluorosuccinic and perfluoroglutaric acid are prepared by dehydration of the acids with phosphorus pentoxide. They are used to prepare the corresponding alcohols by reduction.

8.1.4. Tetrafluoroethylene – Perfluorovinyl Ether Copolymers with Carboxylic Acid Groups

Ion-exchange membranes, used in fuel cells and chloralkali production, are copolymers of tetrafluoroethylene and perfluorovinyl ethers that contain esters or other acid precursor groups [287]. These membranes have excellent thermal and chemical resistance to hot concentrated alkali (up to 40 %).

Production. The vinyl ethers are prepared by the reaction of hexafluoropropylene oxide and methyl-3-fluorocarbonyl perfluoropropionate [285], followed by pyrolysis to give:,

Copolymerization with tetrafluoroethylene followed by saponification produces a polymer with terminal carboxylic acid groups.

Trade Names. Flemion (Asahi Glass), Nafion (DuPont), Neosepta (Tokuyama Soda), and Aciplex (Asahi Chemical).

8.2. Fluorinated Alkanesulfonic Acids

8.2.1. Perfluoroalkanesulfonic Acids

Properties. The first member of the series, trifluoromethanesulfonic acid, was reported in 1954 [288]. Perfluoroalkanesulfonic acids are among the strongest acids known. Conductivity measurements in acetic acid show that the acid strength of trifluoromethanesulfonic acid is comparable to that of fluorosulfonic and perchloric acids [289]. Boiling points are listed in Table 19. Because of their ability to lower surface energy, the longer-chain perfluoroalkanesulfonic acids and sulfonyl fluoride derivatives have found utility as surface-active agents and water repellents and for antisoiling treatment of textiles and fabrics.

Table 18. Physical properties of perfluorodicarboxylic acids

Acid	CAS registry no.	Formula	*mp*, °C	*bp*, °C (kPa)
Perfluoromalonic	[*1514-85-8*]	$CF_2(CO_2H)_2$	117 – 118	
Perfluorosuccinic	[*377-38-8*]	$(CF_2)_2(CO_2H)_2$	86 – 87	150 (2.0)
Perfluoroglutaric	[*376-73-8*]	$(CF_2)_3(CO_2H)_2$	88	134 – 138 (0.4)
Perfluoroadipic	[*336-08-3*]	$(CF_2)_4(CO_2H)_2$	132 – 134	138 (0.5)
Perfluorosuberic	[*678-45-5*]	$(CF_2)_6(CO_2H)_2$	154 – 158	

Table 19. Boiling points of perfluoroalkanesulfonic acids

Acid Formula	CAS registry no.	*bp*, °C (kPa)
CF_3SO_3H	[*1493-13-6*]	60 (0.4)
$C_2F_5SO_3H$	[*354-88-1*]	81 (0.29)
n-$C_4F_9SO_3H$	[*59933-66-3*]	76 – 84 (0.13)
n-$C_5F_{11}SO_3H$	[*3872-25-1*]	110 (0.67)*
n-$C_6F_{13}SO_3H$	[*355-46-4*]	95 (0.46)
n-$C_8F_{17}SO_3H$	[*1763-23-1*]	133 (0.8)

* n-$C_5F_{11}SO_3H \cdot H_2O$

Production. Perfluoroalkanesulfonyl fluorides are usually made by the Simons electrochemical fluorination process (see Section 2.1), in which a hydrocarbon sulfonyl fluoride is electrolyzed in anhydrous hydrogen fluoride at nickel electrodes:

$$C_nH_{2n+1}SO_2F + (2n+1)HF \longrightarrow C_nF_{2n+1}SO_2F + (2n+1)H_2$$

The electrochemical yield is excellent for the first member of the series and decreases progressively with the increasing length of the carbon chain; the yield for octanesulfonyl fluoride is ca. 40 % [271], [290]. Alkaline hydrolysis of perfluoroalkanesulfonyl fluorides gives the corresponding salts, which when acidified and distilled from concentrated sulfuric acid yield the anhydrous sulfonic acids [288].

A nonelectrochemical method for the preparation of trifluoromethanesulfonic acid derivatives is shown below:

$$CF_3SSCF_3 \xrightarrow{Cl_2} 2\,CF_3SCl \xrightarrow[H_2O]{Cl_2} 2\,CF_3SO_2Cl$$

Alkaline hydrolysis, followed by acidification of the sulfonate salt, gives the acid [291].

Uses. Short-chain perfluoroalkanesulfonyl fluorides are used to prepare sulfonamides, which are employed as plant growth regulators and herbicides. Trifluoromethanesulfonic acid is used as an esterification catalyst (FC-24, 3M), and the lithium salt has been investigated as a fuel cell and battery electrolyte (FC-124, 3M). Perfluorobutanesulfonate salts are used as antistatic agents [292], [293]. The higher homologues exhibit good surfactant properties; the derivatives of perfluorohexanesulfonyl fluoride are employed in fire extinguishing formulations. Useful derivatives containing the sulfonamido group can be prepared by reaction of the sulfonyl fluoride with a diamine, followed by quaternization with alkylating agents such as methyl iodide to give a cationic surfactant. As an example, reaction of perfluorohexanesulfonyl fluoride with 3-dimethylaminopropylamine gives

$$C_6F_{13}SO_2NH(CH_2)_3N(CH_3)_3{}^+I^-.$$

The properties related to the low surface energy of the perfluorooctanesulfonyl fluoride, $C_8F_{17}SO_2F$, are utilized in many derivatives. These derivatives include alcohols and their acrylate and methacrylate esters; they are used as comonomers in polymers that impart oil-, water-, and soil-repellent properties to porous substrates such as paper and textiles [294], [295]. A typical reaction sequence for the synthesis of a perfluoroalkanesulfonamide acrylate monomer is shown below:

$$C_8F_{17}SO_2F + RCH_2NH_2 \longrightarrow C_8F_{17}SO_2NHCH_2R$$

$$\xrightarrow{ClCH_2CH_2OH,\ OH^-} C_8F_{17}SO_2N(CH_2R)CH_2CH_2OH$$

$$\xrightarrow{CH_2{=}CHCO_2H} C_8F_{17}SO_2N(CH_2R)CH_2CH_2OCOCH{=}CH_2$$

Perfluoroalkanesulfonamido alcohols are also used as mold-release agents. Esterification with phosphoric acid gives phosphate ester salts of the type

$$[R_fSO_2N(C_nH_{2n+1})CH_2CH_2O]_mPO(ONH_4)_l$$

R_f = perfluoroalkyl; $l = 1, 2$; $m = 1, 2$; and $n = 1, 2$

which are useful oil repellents for paper products [296].

Trade Names. Paper Treatment FC-807, 808 (3M), Textile Treatment Dic-Guard (Dainippon Ink), and Scotchgard (3M).

8.2.2. Fluorinated Alkanedisulfonic Acids

α,ω-Perfluoroalkanedisulfonyl fluorides are prepared by the electrochemical fluorination of hydrocarbon disulfonyl fluorides. The corresponding acids are prepared by alkaline hydrolysis of the fluoride and acidification, or by aqueous permanganate oxidation of the disulfone, $CH_3SO_2(CF_2CF_2)_nSO_2CH_3$ [297]. Distillation of the acids from phosphorus pentoxide yields the cyclic anhydrides [298].

8.2.3. Tetrafluoroethylene – Perfluorovinyl Ether Copolymers with Sulfonic Acid Groups

Ion-exchange membranes are prepared by the copolymerization of tetrafluoroethylene with perfluorovinyl ethers containing sulfonyl halide groups, followed by hydrolysis to yield sulfonic acids. These membranes have excellent chemical and thermal properties similar to those of ion-exchange membranes with terminal carboxylic acid groups (see Section 8.1.4) [299–301].

Production. These ethers are prepared by the condensation of hexafluoropropylene oxide with fluorosulfonyldifluoroacetyl fluoride, FSO_2CF_2COF, which is prepared from C_2F_4 and SO_3, followed by isomerization [302], [303]. Condensation of hexafluoropropylene oxide with γ-fluorosulfonylperfluoroalkyl carbonyl fluorides, $FSO_2(CF_2)_nCOF$ (prepared by electrochemical fluorination of the respective aliphatic sulfone [304], [305]) gives perfluoroether fluorosulfonyl acyl fluorides, e.g., [306]

$$FCOCF(CF_3)O(CF_2CF(CF_3)O)_m(CF_2)_{n+1}SO_2F$$

Subsequent conversion to the vinyl ether

$$CF_2{=}CFO(CF_2CF(CF_3)O)_m(CF_2)_{n+1}SO_2F$$

followed by copolymerization with tetrafluoroethylene gives polymers with fluorosulfonyl side chains, which are hydrolyzed to sulfonate group side-chains [307].

9. Fluorinated Tertiary Amines

Physical Properties. Relative to their molecular mass, perfluoroalkyl-*tert*-amines, like the perfluoroethers, have low boiling points and low freezing or pour points, as shown in Table 20. Low polarity and weak intermolecular forces are responsible for other unusually low values for properties such as viscosity, solubility, heat of vaporization, refractive index, dielectric constant, and surface tension [308]. Some perfluorobis(dialkylaminoalkyl) ethers have even lower pour points and liquid ranges as broad as 250 °C. These ethers exhibit increased internal flexibility through the combined effect of the nitrogen and oxygen atoms [311].

Chemical Properties. Perfluorinated *tert*-amines are chemically inert and thermally stable [308], [312]. The electron-withdrawing nature of the perfluoroalkyl substituents deprives the nitrogen atom of its basic character and reactivity. Fluorinated *tert*-amines do not form salts or complexes with strong acids and are not attacked by most oxidizing or reducing agents. With aluminum chloride they form chlorinated imines [313]. Because of their nonpolar nature, fluorinated *tert*-amines are poor solvents and are immiscible with water and alcohols [308]. Gases such as oxygen, nitrogen, and carbon dioxide have unusually high solubility in perfluorinated *tert*-amines. For example, perfluorotributylamine dissolves 40 vol % of oxygen at ambient conditions and has been used in artificial blood as an effective oxygen-transport medium [313].

Production. Electrochemical fluorination via the Simons process (see Section 2.1) is the preferred route to fluorinated tertiary alkylamines. The hydrogen atoms are completely

Table 20. Physical properties of fluorinated *tert*-amines [308–310]

∗ Freezing point. ∗∗ d_4^{35}

replaced by fluorine atoms. Perfluorotributylamine, for example, is synthesized as follows:,

$$(C_4H_9)_3N + 27\,HF \xrightarrow{e^-} (C_4F_9)_3N + 27\,H_2$$

The crude product contains a significant amount of perfluorinated isomers and cleavage products because of molecular rearrangement during electrolysis; it is purified by fractional distillation and treatment with base.

Uses. The combination of unusual physical and chemical properties, excellent dielectric properties, nonflammability, and lack of toxicity make the perfluorinated *tert*-amines useful for many fluid applications that involve direct contact with sensitive materials [308], [313]. The electronic industry relies heavily on these fluids in reliability testing of electronic components, as direct-contact coolants for integrated circuits, and as heating media in vapor-phase reflow soldering. Perfluorinated tributylamine, triamylamine, and trihexylamine are the main constituents of Fluorinert electronic liquids FC-43, FC-70, and FC-71 (3M).

Information on the preparation and utility of other nitrogen-containing fluoroaliphatic compounds can be found in the general references [1–15].

10. Aromatic Compounds with Fluorinated Side-Chains

The first aromatic compound with a fluorinated side-chain, benzotrifluoride [*98-08-8*], trifluoromethylbenzene, was synthesized in 1898 [314]. The perfluoroalkyl substituents of aromatic compounds are *meta*-directing; this influence can, of cause, be overcome by a stronger *ortho*- or *para*-directing substituent. These compounds are usually prepared from iodoperfluoroalkanes and halogenated aromatic compounds in the presence of a copper catalyst [315–317]. Except for the benzotrifluorides, aromatic compounds with fluorinated side-chains have only scientific interest [318]. Araliphatic compounds with one or two trifluoromethyl substituents on the benzene ring gained commercial importance in the early 1930s for two reasons: 1) the recognition of the advantageous properties of aromatic dyes with CF_3 substituents, and 2) the development of an economical production process [4]. Since then, their importance in the production of dyes, pharmaceuticals, and pesticides has increased.

10.1. Properties

The physical properties of benzotrifluorides are shown in Table 21.

If no other substituents are present in the benzene ring, the trifluoromethyl group is thermally stable up to 350 °C and resistant to bases up to 130 °C. It is inert toward reducing agents [319], [320] and inhibits oxidation of the benzene ring. However, in the presence of aluminum chloride the trifluoromethyl group undergoes chlorolysis to produce a trichloromethyl group [321], and acid hydrolysis forms a carboxy group [322]. Substituents such as amino or hydroxyl groups destabilize the trifluoromethyl group [323].

The characteristic reaction of benzotrifluorides is electrophilic substitution of the benzene ring; chlorination and nitration are commercially important. *Chlorination* of benzotrifluoride at 65 °C with $FeCl_3$ as a catalyst yields 83 % 3-chlorobenzotrifluoride [*98-15-7*] [324]; chlorination of 4-chlorobenzotrifluoride gives 3,4-dichlorobenzotrifluoride [*328-84-7*].

Table 21. Physical properties of benzotrifluorides

Compound	CAS registry number	Empirical formula	M_r	*bp*, °C	d_4^{θ} (θ, °C)	n_D^{θ} (θ, °C)
Benzotrifluoride	[*98-08-8*]	$C_7H_5F_3$	146.11	102.03	1.188 (20)	1.4114 (25)
2-Chlorobenzotrifluoride	[*88-16-4*]	$C_7H_4ClF_3$	180.56	152.5	1.367 (20)	1.4550 (20)
4-Chlorobenzotrifluoride	[*98-56-6*]	$C_7H_4ClF_3$	180.56	140	1.35 (15)	1.4444 (25)
2,4-Dichlorobenzotrifluoride	[*320-60-5*]	$C_7H_3Cl_2F_3$	215.0	117 – 118	1.377 (20)	1.4802 (20)
1,3-Bis(trifluoromethyl)benzene	[*402-31-3*]	$C_8H_4F_6$	214.11	116.1	1.379 (25)	1.3791 (20)
1,4-Bis(trifluoromethyl)benzene	[*433-19-2*]	$C_8H_4F_6$	214.11	117.1	1.381 (25)	1.3792 (20)
3-Trifluoromethylbenzoyl fluoride	[*328-99-4*]	$C_8H_4F_4O$	192.11	159 – 163		1.4350 (20)

Nitration of benzotrifluoride results in a 6 : 3 : 91 mixture of 2-nitro- [*384-22-5*], 4-nitro- [*402-54-0*], and 3-nitrobenzotrifluoride [*98-46-4*] [325]. Other commercially important nitrations are the conversion of 2-chlorobenzotrifluoride [*88-16-4*] to 2-chloro-5-nitrobenzotrifluoride [*777-37-7*] and the conversion of 4-chlorobenzotrifluoride to yield 99 % 4-chloro-3-nitrobenzotrifluoride [*121-17-5*] or 4-chloro-3,5-dinitrobenzotrifluoride [*393-75-9*] [326]. These derivatives are reduced to amines or are further processed.

10.2. Production

Benzotrifluorides are prepared on a laboratory scale by the reaction of aromatic compounds with iodotrifluoromethane [315]; by the reaction of aromatic carboxylic acids and their derivatives with sulfur tetrafluoride [51–53]; or by chlorine – fluorine exchange in trichloromethyl aromatic compounds with metal fluorides [327].

In the commercial process, known since 1931, chlorine is exchanged for fluorine with use of anhydrous hydrogen fluoride in the presence or absence of catalyst [328]:

This reaction can be carried out as a batch process in autoclaves or continuously in a series of autoclaves [329] (Fig. 3) or tubular reactors [330]. Typical conditions for the production of benzotrifluoride are a temperature of 80 – 110 °C, pressure of 1.2 – 1.4 MPa, and a molar ratio of HF : benzotrichloride of 4 : 1. A yield of 70 % is obtained within 3 – 4 h [331]. In continuous processing, a yield of over 90 % is obtained in a nickel flow tube with a residence time of 1 h at 90 – 130 °C and at 3 – 5 MPa [332]. Yields are increased by using additives such as hexamethylenetetraamine [333] or by employing chlorine – fluorine exchange in the gas phase in the presence of a transition metal – aluminum oxide catalyst [334]. Corrosion is reduced by lowering the reaction temperature (< 60 °C) and adding iron or iron compounds [335], [336].

This method is used to produce benzotrifluoride, 2-chlorobenzotrifluoride, 4-chlorobenzotrifluoride, 2,4-dichlorobenzotrifluoride, 1,3-bis(trifluoromethyl)benzene, 1,4-bis(trifluoromethyl)benzene, 3-(trifluoromethyl)benzoyl fluoride, and 4-(trifluoromethyl)benzoyl fluoride [*368-94-5*] from the corresponding trichloromethyl compounds.

The trifluoromethyl group can also be introduced into aromatic compounds by the Friedel – Crafts reaction with carbon tetrachloride in the presence of hydrogen fluoride [337].

R = alkyl, aryl, halogen

10.3. Uses

Benzotrifluoride and 4-chlorobenzotrifluoride are key intermediates for the synthesis of dyes, pharmaceuticals, and pesticides.

Dyes. Trifluoromethyl aromatic compounds were first used in dyes [4] and are still important intermediates for azo, anthraquinone, and triphenylmethane dyes. The strongly electronegative

Figure 3. Production of benzotrifluorides in a series of autoclaves [329]
a) Reactor; b) Pressure distillation column; c) Separator; d) Product distillation column; e) Product storage tank

trifluoromethyl group improves color clarity and fastness to light and washing; it also shifts light absorption to the visible and ultraviolet ranges.

Some of these dye intermediates [338] for the production of anthraquinone and azo dyes (Naphtol AS, Hoechst AG) and azo pigments are still used, especially for polyesters and polyamides. These compounds include 2-aminobenzotrifluoride [*88-17-5*] for C.I. Pigment Yellow 154 [*63661-02-9*]; 3-amino-4-chlorobenzotrifluoride [*121-50-6*] for C.I. Pigment Orange 60 [*68399-99-5*]; 3-(trifluoromethyl)benzoyl fluoride for Indanthren Blue CLB [*6492-78-0*] (BASF) as well as 2-amino-5-chlorobenzotrifluoride [*445-03-4*], 3,5-bis(trifluoromethyl)aniline [*328-74-5*], and 3-amino-4-ethylsulfonylbenzotrifluoride [*382-85-4*].

Pharmaceuticals. The trifluoromethyl substituent is highly lipophilic; it increases the lipid solubility of pharmaceuticals and thus accelerates their absorption and transport in a living organism [339], [340]. In some cases, introduction of the CF_3 group also increases drug effectiveness and reduces undesirable side effects; therefore, benzotrifluorides are used in the synthesis of many pharmaceuticals [341]. These include the analgesics flufenamic acid [*530-78-9*] and niflumic acid [*4394-00-7*], the antidepressant fluoxetine [*54910-89-3*], the muscle relaxant flumetramide [*7125-73-7*], the appetite depressants fenfluramine [*458-24-2*] and fludorex [*15221-81-5*], and the tranquilizers trifluopromazine [*146-54-3*] and fluphenazine [*69-23-8*]. Bendroflumethiazide [*73-48-3*] is an effective diuretic and antihypertensive agent.

Pesticides. Benzotrifluorides are also important in the production of pesticides [342]. The key intermediate, 4-chloro-3,5-dinitrobenzotrifluoride [*393-75-9*], is obtained by dinitration of 4-chlorobenzotrifluoride. Reaction with secondary amines gives trifluralin [*1582-09-8*], profluralin [*26399-36-0*], and benfluralin [*1861-40-1*]. 4-Chlorobenzotrifluoride and 3,4-dichlo-robenzotrifluoride are intermediates for herbicides with a diphenyl ether structure – fluorodifen [*15457-05-3*] and acifluorfen [*50594-66-6*] and the insecticide fluvalinate [*69409-94-5*]. 3-Aminobenzotrifluoride [*98-16-8*] is obtained from benzotrifluoride by nitration and hydrogenation. It is used to make the selective herbicide fluometuron [*2164-17-2*] or is used as a component of the herbicide norflurazon [*27314-13-2*].

11. Ring-Fluorinated Aromatic, Heterocyclic, and Polycyclic Compounds

The compounds discussed in this chapter contain one or more fluorine atoms that are directly attached to aromatic, heterocyclic, or polycyclic rings. Unlike chlorination and bromination, fluorination with elemental fluorine is rarely employed for their production because its violence produces many side reactions (ring-opening, coupling, polymerization, and charring). Therefore, indirect methods are used, distributing the reaction enthalpy over several controllable steps [318].

Diazonium salts are suitable for introducing up to three fluorine atoms per ring. Chlorine – fluorine exchange (halogen exchange, Halex process) with alkali – metal fluorides is suitable in cases where activating substituents are present.

Ring-fluorinated aromatic, heterocyclic, and polycyclic compounds are predominantly used as intermediates for pharmaceuticals, pesticides, dyes and other products. The exceptional properties of fluorinated cyclic compounds (bioactivity spectrum, effectiveness, and solublity) justify the higher production costs compared to those of fluorine-free compounds.

11.1. Mono- and Difluoroaromatic Compounds

Research on ring-substituted aromatic fluorine compounds began in 1870. The fluorine atom attached to the benzene ring is strongly electronegative; it preferentially directs new substituents into the para position and rarely, if ever, into the ortho position [343]. Important aspects, especially for biological applications, are (1) the influence of the strongly electronegative fluorine substituent on adjacent groups, (2) its participation in the resonance system of the aromatic compound by returning electron density, and (3) the simulation of hydrogen or hydroxy substituents that is due to the similarity in space requirements and has led to the synthesis of a series of monofluoro aromatic enzyme inhibitors. The varying lability of the carbon – fluorine bond in mono- and difluoro aromatic compounds has been exploited to prepare indicators and analytical reagents, especially for biogenic and metabolic studies.

11.1.1. Properties

Replacement of aromatic hydrogen by fluorine has only a minor effect on boiling points. Density increases, whereas refractive index and surface tension decrease. Physical constants are shown in Table 22.

The reactivity of fluorine in benzene derivatives depends on the nature of the other ring substituents. Nucleophilic substitution occurs only where activating groups (e.g. nitro) are present in the ortho or para position. In other cases, e.g., with 1-bromo-4-fluorobenzene [*460-00-4*], the carbon – fluorine bond is stronger; hydrolysis gives 4-fluorophenol [*371-41-5*] [344], [345].

11.1.2. Production

Among the published processes for the production of mono- or difluoroaromatic compounds, ring fluorination with dilute fluorine or fluorinating agents such as xenon difluoride [346–349] does not follow a clear course (i.e., without side reactions) and has no commercial value. Fluorobenzene itself can be prepared by pyrolysis of chlorodifluoromethane or chlorotrifluoroethylene in the presence of cyclodipentadiene at 300 – 800 °C [350] and by anodic fluorination of benzene with tetraethylammonium fluoride in acetonitrile [351]. Promising methods are the decarbonylation of benzoyl fluorides in the presence of tris(triphenylphosphine)rhodium(I) chloride in boiling xylene [352] and the thermal decarboxylation of aryl fluoroformates [353].

Diazotization. Aromatic compounds containing one or two fluorine substituents are produced commercially by diazotization of aromatic amines and decomposition of the resulting diazonium fluorides [318],[354]. In one process, aromatic amines are diazotized with dry sodium nitrite in anhydrous hydrogen fluoride at 0 – 20 °C [355] (see Fig. 4).

Table 22. Physical properties of ring-fluorinated aromatic compounds

Compound	CAS registry number	Empirical formula	M_r	*bp*, °C (101.3 kPa)	d_4^{θ} (θ, °C)	n_D^{θ} (θ, °C)

1,4-Difluorobenzene	[*540-36-3*]	$C_6H_4F_2$	114.09	88 – 89	1.176 (20)	1.4421 (20)

∗ At 100.5 kPa

Figure 4. Production of fluoroaromatics by the HF diazotization – dediazoniation method [354]
a) Diazotation reactor; b) Dediazoniation vessel; c) Condenser; d) Separator; e) Distillation column; f) HF purification column; g) Product storage tank

The temperature is increased to 30 – 120 °C, and the formed diazonium fluorides decompose to form fluoroaromatic compounds. A yield of over 90 % of mono- and difluorinated compounds is obtainable. Yields of ca. 81 % are reported for batch operations on a 1-t scale.

In a continuous process the three exothermic steps are controlled by separation; i.e., hydrofluorination of the aromatic amine, diazotization, and thermal decomposition [356]. This permits safe operation on a large scale. Diazotization with nitrosyl chloride [357] and nitrosyl fluoride – HF complexes [358] is also possible. Problems associated with these processes are hydrogen fluoride recovery and waste gas treatment.

In another method (Balz – Schiemann reaction), water-insoluble diazonium fluoroborates are prepared by diazotization of aromatic amines with sodium nitrite in the presence of 40 % fluoroboric acid or sodium or ammonium tetrafluoroborate in HCl [327], [359]. After filtration the diazonium salts are dried and thermolyzed [360] (Fig. 5):

Figure 5. Production of fluoroarmatics by the Balz – Schiemann method
a) Stirred diazotization reactor; b) Storage for 50 % HBF_4; c) Filter; d) Drier; e) Mixer; f) Dediazoniation reactor; g) Condenser; h) Separation column; i) Product distillation column; k) Product storage tank

This thermal decomposition must be strictly controlled, especially when nitro substituents are present, to avoid an explosion. Diazonium tetrafluoroborates usually decompose at a higher temperature than the corresponding diazonium fluorides. The Balz – Schiemann process has rarely been used on a large scale because of the difficulties in handling diazonium tetrafluoroborates. However, it is convenient as a laboratory process because it does not require specialized apparatus. A plant of several 100 t/a has been reported [361].

A large number of fluoroaromatic compounds have been produced by using the two diazotization routes described [327], [362]. Those of commercial interest include fluorobenzene from aniline; 2-, 3-, and 4-fluorotoluene from the appropriate toluidines; 4,4′-difluorodiphenylmethane from 4,4′-diaminodiphenylmethane; 1,3-difluorobenzene from *m*-phenylenediamine; and 1,4-difluorobenzene from *p*-phenylenediamine.

The reaction sequence of nitration, reduction, diazotization, and thermal decomposition can be repeated to introduce up to four fluorine atoms into the benzene ring.

Chlorine – Fluorine Exchange. Of similar commercial importance to diazotization is the replacement of activated chlorine atoms with the aid of alkali-metal fluorides [318], [354]. The usual activating groups are *ortho* and *para* nitro, cyano, and trifluoromethyl groups [363]. Aprotic – polar solvents are preferred, such as dimethylformamide, dimethylacetamide, dimethyl sulfoxide, *N*-methyl-2-pyrrolidone, and tetrahydrothiophene-1,1-dioxide (sulfolane).

R = NO_2, CN, CF_3; M = K, Cs

Phase-transfer catalysts are sometimes used [364]. The effectiveness of the fluoride source decreases in the order CsF > KF > NaF > LiF.

In commercial batch or semicontinuous operations, the *Halex process* (Fig. 6), potassium fluoride and the activated chloroaromatic compound are thoroughly mixed (1 : 1) with a large volume of an aprotic solvent (dimethyl sulfoxide or sulfolane) and are heated to 150 – 250 °C [363], [365]. The reaction is 90 % complete within 48 h. Removal of KCl and distillation of the product present no difficulty, but efficient solvent recovery is important to reduce costs.

Cost is also reduced by regenerating the potassium fluoride by treating the KCl with HF [366]. The Halex process has the clear advantage of readily accessible raw materials, simplicity of a single-step procedure, and structural specificity. Certain products are accessible in no other way.

Figure 6. Flow sheet of the Halex process for the manufacture of fluoronitrobenzene [363]
a) Reactor; b) Distillation column; c) Condenser; d) Drier; e) Product distillation column; f) Product storage tank; g) Condenser for off-gas

The following commercially important intermediates are obtained by the Halex process: 1-fluoro-2-nitrobenzene [*1493-27-2*] and 1-fluoro-4-nitrobenzene [*350-46-9*] from the corresponding chloronitrobenzenes;1-chloro-2-fluoro-5-nitrobenzene [*350-30-1*] from 1,2-dichloro-4-nitrobenzene;1-chloro-4-fluoro-3-nitrobenzene [*345-18-6*] from 1,4-dichloro-2-nitrobenzene;1-fluoro-2,4-dinitrobenzene [*70-34-8*] from 1-chloro-2,4-dinitrobenzene;5-fluoro-2-nitrobenzotrifluoride [*393-09-9*] from 5-chloro-2-nitrobenzotrifluoride [*118-83-2*]; 1,3-difluoro-4-nitrobenzene [*446-35-5*] from 1,3-dichloro-4-nitrobenzene; and 2,6-difluorobenzonitrile [*1897-52-5*] from 2,6-dichlorobenzonitrile. These intermediates are mostly used for substituted anilines and compounds with carbonyl and carboxy functions.

11.1.3. Uses

Fluorobenzene, difluorobenzenes, and their derivatives are used widely in the synthesis of pharmaceuticals and pesticides, and as fine chemicals. Fluoroaromatics have played a special role in the development of drugs that act on the central nervous system [367]. The increase in lipid solubility due to fluorine atoms facilitates the absorption and transport of drugs through the blood – brain barrier into the central nervous system.

Fluorobenzene derivatives are used in neuroleptics such as haloperidol [*52-86-8*], tranquilizers such as fluspirilene [*1841-19-6*], sedatives such as flurazepam [*17617-23-1*], and antidepressants such as fluroxamin [*54739-18-3*].

Pesticidal [342] and fungicidal fluorobenzene derivatives [368] include the insecticide diflubenzuron [*35367-38-5*] (made from 2,6-difluorobenzonitrile), the herbicides flamprop [*58677-63-3*] and fluoronitrofen [*13738-63-1*], and the fungicides nuarimol [*63284-71-9*] and flurimid [*41205-21-4*].

4,4′-Difluorobenzophenone [*345-92-6*], a starting material for aromatic polycondensates, is produced by oxidation of 4,4′-difluorodiphenylmethane, which is obtained by diazotization of the corresponding diamine. 4,4′-Difluorobenzophenone undergoes polycondensation with hydroquinone, yielding a polyetherether ketone (PEEK) resin, a thermoplastic. 4-Fluoroaniline [*371-40-4*], 4-fluorobenzaldehyde [*459-57-4*], and 4-fluorobenzoic acid [*456-22-4*] are intermediates for liquid crystal polymers [369].

Aromatic compounds with reactive fluorine substituents are used for the characterization of amino acids (Sanger's reagent, 1-fluoro-2,4-dinitrobenzene [*70-34-8*]), the immobilization of enzymes (4-fluoro-3-nitrophenylazide [*28166-06-5*]), and peptide cross-linkage (1,5-difluoro-2,4-dinitrobenzene [*327-92-4*]).

Aromatic fluorine compounds have been developed for medical applications, such as ^{19}F-magnetic resonance imaging (MRI) and in ^{18}F-positron emission tomography (PET) [370].

11.2. Highly Fluorinated Aromatic Compounds

Compounds in which an aromatic ring is substituted by three to five fluorine atoms have little commercial importance. 1,2,4-Trifluorobenzene [*367-23-7*], *bp* 88 °C, and 1,3,5-trifluorobenzene [*372-38-3*], *bp* 75.5 °C, are produced by the Balz–Schiemann reaction (see Section 11.1.2) from 2,4-difluoroaniline [*367-25-9*] and 3,5-difluoroaniline [*372-39-4*], respectively. 1,3,5-Tricyano-2,4,6-trifluorobenzene [*3638-97-9*], *mp* 148–150 °C, is used as an intermediate for pesticides; it is obtained by chlorine–fluorine exchange from 1,3,5-tricyano-2,4,6-trichlorobenzene [371].

1,2,3,5-Tetrafluorobenzene [*2367-82-0*], *bp* 83 °C, is obtained by the Balz–Schiemann reaction from 2,3,5-trifluoroaniline [*363-80-4*], and 1,2,4,5-tetrafluorobenzene [*327-54-8*], *bp* 90 °C, from 2,4,5-trifluoroaniline [*57491-45-9*]. 1,2,3,4-Tetrafluorobenzene [*551-62-2*], *bp* 95 °C, pentafluorobenzene [*363-72-4*], *bp* 85 °C, and hexafluorobenzene are produced by the CoF_3 method (see Section 11.3).

The Halex process (Section 11.1.2) is used commercially to produce 1,4-dicyano-2,3,5,6-tetrafluorobenzene [*1835-49-0*], *mp* 197–199 °C, from the corresponding tetrachloro derivative [372]. This compound is used as a monomer for thermostable polymers.

11.3. Perhaloaromatic Compounds

Hexafluorobenzene [*392-56-3*], *bp* 80.3 °C, has been thoroughly investigated [373]. Nucleophilic substitution produces pentafluoroaromatic compounds such as

bromopentafluorobenzene [*344-04-7*], *bp* 135.6 °C
pentafluorophenol [*771-56-2*], *bp* 117–118 °C
pentafluoroaniline [*771-60-8*], *bp* 153 °C
pentafluorobenzene [*771-61-9*], *bp* 143 °C
pentafluorotoluene [*771-56-2*], *bp* 117 °C
pentafluorobenzaldehyde [*653-37-2*], *bp* 164–166 °C
pentafluorobenzoic acid [*602-94-8*], *bp* 220 °C

Production. Hexafluorobenzene was first produced in 1955 by pyrolysis of tribromofluoromethane [*353-54-8*] in a platinum tube at 640 °C under atmospheric pressure [374]:,

$$6\,CBr_3F \longrightarrow C_6F_6 + 9\,Br_2$$

Of greater commercial interest is the pyrolysis of an equimolar mixture of dichlorofluoromethane [*75-43-40*] and chlorofluoromethane [*593-70-4*] at 600–800 °C [375]:

$$3\,CHCl_2F + 3\,CH_2ClF \longrightarrow C_6F_6 + 9\,HCl$$

For many years a commercial multistep process employed CoF_3 as the fluorinating agent [376]. For example, at 150 °C benzene gives a mixture of cyclohexanes containing 8–11 fluorine atoms.

$$C_6H_6 \xrightarrow[CoF_2]{CoF_3} C_6H_{12-n}F_n \xrightarrow{MOH} C_6H_{11-n}F_{n-1} + C_6H_{10-n}F_{n-2} \xrightarrow{Fe\ or\ Fe_3O_4} C_6F_6,\ C_6HF_5,\ C_6H_2F_4$$

$n = 8-11$,
M = alkali metal

The CoF_2 formed in this reaction is fluorinated to CoF_3 with elemental fluorine, and reused. The organic products are heated with an alkali-metal hydroxide to form a mixture of polyfluorocyclohexenes and polyfluorocyclohexadienes. These products are aromatized by passage over iron or iron compounds at 400–600 °C to give hexafluorobenzene, pentafluorobenzene, and tetrafluorobenzenes. Octafluorotoluene [*434-64-0*] and the three perfluoroxylenes are also obtained by this method.

The disadvantages of this process are the technological difficulties and the low utilization of fluorine, of which a large part is converted to hydrogen fluoride and alkali-metal fluorides. As a consequence, aromatic fluorine compounds containing other halogens are currently produced by the Halex method (Section 11.1.2). Reaction of hexachlorobenzene [365] with potassium fluoride at 450 °C and 1.03 MPa gives a yield of 21 % hexafluorobenzene together

with chloropentafluorobenzene [*344-07-0*] (20 %), 1,3-dichloro-2,4,5,6-tetrafluorobenzene [*1198-61-4*] (14 %), and 1,3,5-trichloro-2,4,6-trifluorobenzene [*319-88-0*] (12 %).

$$C_6Cl_6 + KF \longrightarrow C_6F_6,\ C_6ClF_5,\ C_6Cl_2F_4,\ C_6Cl_3F_3$$

The yield of hexafluorobenzene can be increased by recycling the other products for further reaction with potassium fluoride. A yield of 42 % hexafluorobenzene is obtained from chloropentafluorobenzene with the more reactive, but more expensive, cesium fluoride [377].

Hexachlorobenzene reacts with KF in aprotic solvents such as dimethylformamide, dimethyl sulfoxide, *N*-methyl-2-pyrrolidone, and sulfolane to give not hexafluorobenzene, but the above-mentioned mixed products. The reaction temperature is 150 – 250 °C and the residence time 5 – 36 h. Detailed discussions of the process are given in [363], [365].

Uses. Hexafluorobenzene has been investigated as an inhalation anesthetic in veterinary medicine [378] and as a working fluid in Rankine-cycle engines for temperatures above 350 °C [379]. Derivatives such as pentafluorobenzaldehyde or pentafluorophenyl dimethylsilyl ether are used in the chromatographic analysis of steroids [380] and catecholamines [381], and as intermediates for the production of liquid crystal polymers [382]. Pentafluorophenoxy perfluorovinyl ethers are cross-linking comonomers for perfluorinated elastomers [383].

11.4. Fluorinated Heterocyclic and Polycyclic Compounds

Fluorinated pyridines, pyrimidines, and triazines are heterocycles with commercial importance. Only some representative polycyclic fluorine compounds are discussed as examples.

11.4.1. Ring-Fluorinated Pyridines

Introduction of fluorine into the pyridine ring reduces the basicity of the latter [384]. 2-Fluoropyridine [*372-48-5*], *bp* 126 °C (100.4 kPa), has a labile fluorine substituent. It is produced in 74 % yield by reaction of 2-chloropyridine with potassium bifluoride at 315 °C in 4 h [385]. 3-Fluoropyridine [*372-47-4*], *bp* 105 – 107 °C (100.3 kPa), is produced in 50 % yield from 3-aminopyridine using the Balz – Schiemann process (see page 39). 4-Fluoropyridine [*694-52-0*], *bp* 108 °C (100 kPa) is produced in 54 % yield by diazotization of 4-aminopyridine in anhydrous hydrogen fluoride [386].

2,4-Difluoropyridine [*34941-90-7*], *bp* 104 – 105 °C, is obtained by the Halex process (see page 41) from 2,4-dichloropyridine and potassium fluoride in sulfolane [387]. 2,6-Difluoropyridine [*1513-65-1*], *bp* 124.5 °C (99.1 kPa), is obtained by the reaction of 2,6-dichloropyridine with potassium fluoride in the absence of solvent. The yield is 80 % after 18 h at 400 °C [388].

For pentafluoropyridine [*700-16-3*], *bp* 83 °C, the preferred method is the reaction of pentachloropyridine with KF at 480 – 500 °C; the yield is 83 % [389]. Nucleophilic substitution reactions have been thoroughly investigated [390].

Uses. Fluoropyridines are intermediates for pesticides. For example, 2-fluoro-4-hydroxypyridine [*22282-69-5*] is a precursor of 2-fluoro-3,5-dihalo-4-hydroxypyridine herbicides [391]; 2-fluoro-6-hydroxypyridine [*55758-32-2*] is used for insecticides and nematocides [392] and various derivatives of fluorinated pentahalogenpyridine herbicides [393]. Pentafluoropyridine in mixtures with hexafluorobenzene is used as the working fluid in Rankine-cycle engines up to 382 °C [379].

11.4.2. Trifluoromethylpyridines

2-Trifluoromethyl- [*368-48-9*], 3-trifluoromethyl- [*3796-23-4*], and 4-trifluoromethylpyridine [*3796-24-5*] can be obtained by the reaction of picolinic, nicotinic, or isonicotinic acid, respectively, with sulfur tetrafluoride [394]. Commercial processes use side-chain chlorination of the methylpyridines followed by chlorine – fluorine exchange with antimony chlorofluorides or anhydrous hydrogen fluoride [395]. 2-Chloro-5-trifluoromethylpyridine,

bp 190 °C, is produced commercially from 2-chloro-5-trichloromethylpyridine and hydrogen fluoride at 180 – 200 °C and at a pressure of 3 – 4.5 MPa. It is an intermediate for the synthesis of the selective herbicide fluazifop [*69335-91-7*], [396].

11.4.3. Fluoropyrimidines

Certain fluoropyrimidines have gained commercial importance [397]. 5-Fluoropyrimidines are employed in cancer chemotherapy; their biochemistry and pharmacology have been intensively studied [398]. 5-Fluorouracil [*51-21-8*] is obtained in a 80 – 92 % yield by the fluorination of 2,4-dihydroxypyrimidine with fluorine or trifluoromethyl hypofluorite [399], [400].

5-Chloro-2,4,6-trifluoropyrimidine [*697-83-6*], *bp* 114.5 °C (100 kPa), is produced commercially from 2,4,5,6-tetrachloropyrimidine by chlorine – fluorine exchange, using sodium fluoride at 300 °C [401] or anhydrous hydrogen fluoride in the liquid phase [402] or gas phase [403].

The 5-chloro-2,4-difluoropyrimidinyl radical acts as the reactive group in reactive dyes [397] for cellulose and cotton fibers such as Levafix EA (Bayer) and Drimarene K (Sandoz) and for wool, e.g., Verofix (Bayer) and Drimalene (Sandoz).

11.4.4. Fluorotriazines

2,4,6-Trifluoro-1,3,5-triazine [*675-14-9*], *bp* 72.4 °C (101.7 kPa), is produced commercially from 2,4,6-trichloro-1,3,5-triazine (cyanuric chloride) with either anhydrous hydrogen fluoride [404] or sodium fluoride in sulfolane [405]. It is used to manufacture reactive dyes by reaction between one or two fluorine substituents with amino groups of chromophores; the remaining fluorine binds to the fiber [406]. The reactive intermediates can be synthesized e.g., from the corresponding 6-substituted 2,4-dichlorotriazines and an alkali-metal fluoride or by reaction of cyanuric fluoride with anilines or phenols in organic solvents [406], [407]. Like the pyrimidine reactive dyes, the fluorotriazines are used on cellulose, polyesters, polyamides, and wool [397]. See also → Reactive Dyes.

11.4.5. Polycyclic Fluoroaromatic Compounds

Polycyclic fluoroaromatic compounds are used as intermediates for the production of pharmaceuticals.

4-Fluoro- [*324-74-3*] and 4,4′-difluorobiphenyl [*398-23-2*] are obtained by diazotization from the corresponding amines in yields of up to 80 % [408]. Other biphenyl derivatives are prepared from fluorobenzenes. The analgesic diflunisal [*22494-42-4*] is produced from 2,4-difluoroaniline [*367-25-9*] by diazotization and coupling with salicylic acid. The anti-inflammatory drugsflurbiprofen [*5104-49-4*] and fluprofen [*17692-38-5*] are prepared from 2-fluoroaniline [*348-54-9*].

The anti-inflammatory drug sulindac [*38194-50-2*] is a monofluorinated indole-3-acetic acid.

12. Economic Aspects

The compounds discussed in Chapters 10 and 11 are not produced in large quantities and often command high prices. 4-Chlorobenzotrifluoride, 3,4-dichlorobenzotrifluoride, 3-trifluoromethylphenyl isocyanate, and benzotrifluoride are produced in the United States by Occidental Chemical, in Western Europe by Hoechst, Rhône-Poulenc, MitEni and Dow-Elanco, and in Japan by Daikin. The worldwide production capacity is ca. 35 000 – 40 000 t/a.

Heterocyclic fluorine compounds have economic importance in the production of reactive dyes. The main producers in Western Europe are Bayer AG, Ciba-Geigy, ICI, and Sandoz.

Fluorobenzene and its derivatives are produced in Western Europe by AlliedSignal – Riedel-de-Haën (production capacity 1600 t/a), Zeneca (2000 – 2500 t/a), Rhône-Poulenc (1000 t/a), MitEni (1000 t/a) in Europe, DuPont (1400 t/a), Mallinckrodt (1200 t/a) in the USA and Asahi Glass (1000 t/a) in Japan. Fluoronitrobenzenes and fluoroanilines are produced by the Halex process by Hoechst, MitEni, Rhône-Poulenc, Asahi Glass, and others. The total capacity for fluoroaromatic intermediates is estimated to be several thousand tons per year.

13. Toxicology and Occupational Health

With few exceptions, organic fluorine compounds are physiologically inert and display insignificant toxicity. This is a consequence of the chemical stability of the carbon – fluorine bond and the increased stability of hydrogen and halogen bonds attached to a fluorinated carbon atom. Low toxicity is an important factor in many applications of these compounds.

The difference in toxicity between a chloro or bromo compound and the corresponding fluoro compound is often striking. Thus, carbon tetrachloride [*56-23-5*] is a powerful liver and kidney toxin and a weak carcinogen, as reflected in its TLV of 5 ppm. However, the product obtained by replacing one chlorine atom with fluorine, trichlorofluoromethane [*75-69-4*], has no adverse effects on the liver, kidney, or other organs, and no carcinogenic effects on animals exposed to high concentrations for a lifetime; the TLV is 1000 ppm. Another example is the chemical warfare agent mustard gas, $S(CH_2CH_2Cl)_2$ [*505-60-2*], which is a strong alkylating agent and notorious vesicant. The fluoro analog, bis(2-fluoroethyl) sulfide [*373-25-1*], is chemically and physiologically inert, with no vesicant properties [409].

The few highly toxic organofluorine compounds usually have easily replaceable fluorine atoms. Examples are diisopropyl fluorophosphate [*55-91-4*], a potent cholinesterase inhibitor, and perfluoroisobutylene [*382-21-8*], which causes pulmonary edema at low concentrations. Sodium fluoroacetate [*62-74-8*], a potent rodenticide, is an exception; it does not liberate fluorine, but interferes with metabolism by mimicking acetic acid.

13.1. Fluorinated Alkanes

Fluoroalkanes [410], [411]. Perfluoroalkanes have very low toxicity. Thus, rats exposed to an 80 : 20 mixture of perfluorocyclobutane [*115-25-3*] and oxygen for 4 h survived with no ill effects. Likewise, no ill effects were seen in four species of animals exposed to a 10 % concentration in air 6 h/d for 90 d. Partially fluorinated alkanes have similarly low toxicity, as shown by similar experiments with difluoromethane [*75-10-5*] and1,1-difluoroethane [*75-37-6*].

Chlorofluoroalkanes are more toxic than the corresponding fluoroalkanes; nevertheless, most chlorofluoroalkanes have low toxicity [410–412]. High concentrations (10 – 50 % in air) of many of them, like lower concentrations of many hydrocarbon and chlorohydrocarbon solvents, can cause cardiac sensitization, i.e., sensitization of the heart to the body's adrenalin. This can lead to cardiac arrhythmia (heartbeat irregularity) and sometimes cardiac arrest. Deaths have been caused by "aerosol sniffing".

The toxicity of dichlorodifluoromethane [*75-71-8*] has been thoroughly investigated. Rats survived a 6-h exposure to an 80 % mixture with oxygen. Five species of animals continuously exposed to 810 ppm for 90 d showed no effects except for slight liver damage in guinea pigs. Rats and dogs showed no significant health effects when fed a diet containing 0.3 % for 2 years. Teratogenic and reproductive tests in rats were also negative. Repeated exposure caused little or no irritation to rat skin or the rabbit eye. In a screening test, dogs injected with adrenalin showed cardiac sensitization on exposure to 50 000 ppm in air, but not to 25 000. On the basis of animal data and human experience, a TLV of 1000 ppm has been selected to provide an ample margin of safety against cardiac sensitization and other injury [413]. The MAK is also 1000 ppm [414].

Compared to dichlorodifluoromethane, trichlorofluoromethane [*75-69-4*] and 1,1,2-trichloro-1,2,2-trifluoroethane [*76-13-1*] are slightly more toxic, whereas 1,2-dichloro-1,1,2,2-tetrafluoroethane [*76-14-2*] is slightly less toxic. However, for all three a TLV of 1000 ppm is judged to provide an adequate margin of safety. On the other hand, 1,1,1,2-tetrachloro-2,2-difluoroethane [*76-11-9*] and 1,1,2,2-tetrachloro-1,2-difluoroethane [*76-12-0*] cause liver and lung damage to rats subjected to repeated exposure at 1000 ppm; therefore, a TLV of 500 ppm is recommended for these compounds. These data indicate that the toxicity of chlorofluorocarbons tends to increase with the chlorine : fluorine ratio and the number of carbon atoms.

Although the toxicity of most chlorofluoroalkanes bearing hydrogen (chlorofluorohy-

drocarbons) is also low, it tends to be higher than that of the closely related chlorofluorocarbons. The difference is usually slight, as in the case of 2-chloro-1,1,1,2-tetrafluoroethane [*2837-89-0*], which is a slightly stronger cardiac sensitizer than 1,2-dichloro-1,1,2,2-tetrafluoroethane, but is otherwise similar to it in toxic properties. Chlorodifluoromethane [*75-45-6*] is similar in toxicity to dichlorodifluoromethane in most respects, and has the same TLV of 1000 ppm. At 50 000 ppm it has a weak carcinogenic effect in male rats, but not at lower concentrations or in mice or female rats; therefore, this is considered of no practical significance [415].

The toxicity of dichlorofluoromethane [*75-43-4*] is more like that of chloroform than of dichlorodifluoromethane or chlorotrifluoromethane [*75-72-9*], especially with respect to injury on repeated exposure; its TLV, 10 ppm, is low for a chlorofluoroalkane.

Bromofluoroalkanes, some of which are fire extinguishing agents and anesthetics, are more toxic than the corresponding chlorofluoroalkanes, but generally are low in toxicity compared to other fire extinguishing agents and anesthetics [409], [413]. Trifluorobromomethane [*75-63-8*] produced no adverse effects on dogs and rats exposed to 23 000 ppm 6 h/d, 5 d/week, for 18 weeks; its TLV is 1000 ppm [413].

13.2. Fluorinated Olefins

Most fluorinated olefins have halogen atoms of low reactivity and a correspondingly low-to-moderate toxicity [409], [412]. The toxicities of the five most common members of the class, typical in these respects, are shown in Table 23.

Table 23. Toxicities of fluorinated olefins∗

Compound	CAS registry no.	Lethal conc., ppm
Vinyl fluoride	[*75-02-5*]	> 800 000 (ALC)∗∗
Vinylidene fluoride	[*75-38-7*]	> 800 000 (ALC)∗∗
Tetrafluoroethylene	[*116-14-3*]	40 000 (LC_{50})
Hexafluoropropene	[*116-15-4*]	3 000 (LC_{50})
Chlorotrifluoroethylene	[*79-38-9*]	1 000 (LC_{50})

∗ Inhalation by rats, 4-h exposure.
∗∗ Approximate lethal concentration.

In perfluoroisobutylene and 2,3-dichloro-1,1,1,4,4,4-hexafluoro-2-butene [*303-04-8*], halogens are readily displaced by nucleophilic reactants; thus, these two compounds exhibit high acute toxicity. Perfluoroisobutene, with a LC_{50} of 0.5 ppm, acts much like phosgene in causing death by pulmonary edema. However, perfluoroisobutene is ca. 10 times as toxic as phosgene, so exposure to it must be carefully avoided. Pyrolysis of tetrafluoroethylene or its polymers above 400 °C is one of its sources.

13.3. Fluorinated Alcohols

2-Fluoroethanol [*371-62-0*] has a high acute toxicity (LD_{50} 10 mg/kg), a consequence of its ready biological oxidation to fluoroacetic acid (see Section 13.6). Thus, contact with the skin and inhalation of vapors must be avoided. The di- and trifluoroethanols ([*359-13-7*] and [*75-89-8*], respectively) have relatively low acute toxicity, similar to the corresponding acetic acids [412]. The acute toxicity of 1,1,1,3,3,3-hexafluoro-2-propanol [*920-66-1*] is also low, but the substance is a strong skin and eye irritant.

13.4. Fluorinated Ketones

In 90-d inhalation studies in animals, hexafluoroacetone [*684-16-2*] caused severe damage to kidneys and other organs at 12 ppm, moderate damage at 1 ppm, and no damage at 0.1 ppm. Repeated skin exposure led to testicular damage in rats. These data and plant experience led to selection of a TLV of 0.1 ppm, with a warning against skin exposure [413]. Studies of hexafluoroacetone and three fully halogenated chlorofluoroketones indicated moderate acute toxicity [416].

13.5. Fluorinated Carboxylic Acids

Fluoroacetic acid [*144-49-0*] is highly toxic to mammals; its sodium salt is an effective, but indiscriminate, rodenticide; in rats the LD_{50} of the salt is only 1.7 mg/kg [413]. In contrast, difluoroacetic acid [*381-73-7*] and perfluoroalkanoic acids have low acute toxicity.

The unusually high toxicity of fluoroacetic acid compared to the more highly fluorinated acids is due to its unique ability to interfere with the citric acid cycle, the oxidation pathway used for energy production from amino acids, fatty acids, and carbohydrates. Fluoroacetic acid enters the cycle at the same site as acetic acid and is converted to fluorocitric acid [*387-89-1*] analogously to the conversion of acetic acid to citric acid. The fluorocitric acid inhibits aconitase, a key enzyme for the breakdown of citric acid, with the result that the citric acid concentration soon rises to lethal levels [417].

Substances that yield fluoroacetic acid on biochemical oxidation, such as straight-chain, even-numbered, ω-fluoro alcohols or alkanoic acids, are also very toxic.

13.6. Other Classes

Simple perfluoroethers, and the oily oligomers of hexafluoropropylene oxide with modified end groups, have the low toxicity expected from their chemical inertness. Hexafluoropropylene oxide itself, a reactive substance, is moderately toxic to rats (4-h LC_{50}, 3700 ppm) [418]. Several partially fluorinated ethers are used as anesthetics, e.g., Enflurane [*13838-16-9*], F_2CHOCF_2CHFCl, and Methoxyflurane [*76-38-0*], $CH_3OCF_2CHCl_2$. Their toxicity is low compared to that of most anesthetics (→ Anesthetics, General, Chap. 1.).

Perfluorinated tertiary aliphatic amines are inert both chemically and biologically. This is illustrated by perfluorotripropylamine [*338-83-0*]; in emulsion with perfluorodecalin [*306-94-5*], it has shown promise as a blood substitute in clinical trials [419].

Fluorine substituents usually have little effect on the toxicity of aromatic compounds, whether monocyclic, polycyclic or heterocyclic [416].

1. Introduction

History. The fluoropolymer industry owes its start to a fortunate accident in Du Pont's Jackson Laboratory in 1938. Roy Plunkett was attempting to prepare new refrigerant gases from tetrafluoroethylene (TFE). However, one morning, when the valve to the almost full TFE cylinder was opened, no gas came out. After being satisfied that the valve had not malfunctioned, he had the cylinder cut open. What he found was the first sample of polytetrafluoroethylene (PTFE), a remarkable polymer, which has become an essential material in the world today. Initially, no applications were known for this new material. However, the Manhattan Project of World War II required a material sufficiently resistant to the highly corrosive substance UF_6, an intermediate in the production of ^{235}U-enriched uranium. Polytetrafluoroethylene appeared to fill this need, spurring the development of processing and production methods for the new fluoroplastic. In 1946, PTFE was introduced commercially under the tradename Teflon. This new plastic, with its outstanding chemical, electrical, and surface properties, gained immediate acceptance in the marketplace. Since then, other fluoropolymers have been discovered and commercialized. These products include fluoroplastics and fluoroelastomers and serve an ever-expanding market, providing materials with the unique combination of properties which fluoropolymers alone can provide.

Monomers. Only four fluoroolefins have been polymerized to high molecular mass homopolymers of commercial importance. These monomers are tetrafluoroethylene (TFE), vinyl fluoride (VF), vinylidene fluoride (VDF or VF_2), and chlorotrifluoroethylene (CTFE). However, other monomers have been copolymerized with these fluoroolefins. Such copolymers have created a diversity of commercially available fluoropolymers, including both plastics and elastomers. The principal monomers from which most commercial fluoropolymers are made are listed in Table 1. The fluoromonomers are described in detail elsewhere in this volume (→ Fluorine Compounds, Organic). Several other monomers are used in small amounts as modifiers and to provide cure sites.

Polymers. Among the fluoroplastics (semicrystalline polymers with $mp > 150\,°C$), several forms of PTFE and a variety of TFE copolymers are commercially available. Others are based on VF, VDF, and CTFE. In the case of fluoroelastomers (amorphous polymers with $T_g < 0\,°C$), VDF–HFP (hexafluoropropylene) copolymers and VDF–HFP–TFE terpolymers constitute the bulk of today's commercial products. Other important fluoroelastomers include TFE copolymers with propene (TFE–P), and perfluoro(methyl vinyl ether), (TFE–PMVE), fluorosilicones, and fluorophosphazenes. A special group of TFE copolymers that contain sulfonic acid and carboxylic acid functions are commercially available in the form of ion-exchange membranes (→ Fluorine Compounds, Organic, Chap. 8.2.).

Production. The principal method for synthesizing organic fluoropolymers is free-radical polymerization. Because of the electrophilic nature of fluoroolefins, cationic polymerization catalysts are not effective. Fluoroolefins and epoxides can be polymerized by anionic catalysts, but termination by fluoride ion elimination prevents high molecular masses from being attained. Coordination catalysts do not effect polymerization of fluoroolefins.

The polymerization and processing techniques described in this article are described in

Table 1. Monomers used in commercial fluoropolymers

Compound	CAS registry number	Formula	Abbreviation
Ethylene	[*74-85-1*]	$CH_2{=}CH_2$	E
Tetrafluoroethylene	[*116-14-3*]	$CF_2{=}CF_2$	TFE
Chlorotrifluoroethylene	[*79-38-9*]	$CF_2{=}CClF$	CTFE
Vinylidene fluoride	[*79-38-7*]	$CF_2{=}CH_2$	VDF (VF_2)
Vinyl fluoride	[*75-02-5*]	$CFH{=}CH_2$	VF
Propene	[*115-07-1*]	$CH_3CH{=}CH_2$	P
Hexafluoropropene	[*116-15-4*]	$CF_3CF{=}CF_2$	HFP
Perfluoro(methyl vinyl ether)	[*1187-93-5*]	$CF_3OCF{=}CF_2$	PMVE
Perfluoro(propyl vinyl ether)	[*1623-05-8*]	$CF_3CF_2CF_2OCF{=}CF_2$	PPVE

detail elsewhere (→Polymerization Processes, → Plastics, Processing).

Properties. The properties of fluoropolymers vary with the fluorine content and with the distribution of fluorine atoms in the molecule. The carbon–fluorine bond is one of the strongest organic bonds. Substitution of fluorine for hydrogen in a hydrocarbon polymer generally increases chemical and oxidative stability, weatherability, and melting point. The presence of fluorine reduces flammability, solubility in hydrocarbons, adhesiveness, radiation resistance, and the coefficient of friction. Each fluoropolymer has its own unique combination of properties. Cost generally increases with fluorine content.

Uses. Numerous uses have been found for fluoropolymers, many of which cannot be satisfied by any other material.

Fluoroplastics find their greatest utility in electrical applications such as insulation, flexible printed circuits, and piezoelectric devices. Other applications include chemically resistant coatings, bearings, nonstick surfaces, architectural fabric (dome construction), laboratory ware, heat exchangers, heart valves and other prosthetic devices, and water-repellent fabric.

Fluoroelastomers have found their greatest use in sealing applications, such as O-rings, gaskets, valve stem seals, and shaft seals. They are also used in flue duct expansion joints, as linings for fuel hoses, binders for military flares, and processing aids for polyethylene film extrusion.

2. Fluoroplastics

2.1. Introduction

The family of thermoplastic fluoropolymers is headed by polytetrafluoroethylene (PTFE). Other members include TFE−HFP copolymers (FEP), TFE−PPVE copolymers (PFA), and TFE−ethylene copolymers (ETFE), as well as polychlorotrifluoroethylene (PCTFE) and CTFE−ethylene copolymers (ECTFE). Poly(vinyl fluoride) (PVF), poly(vinylidene fluoride) (PVDF), and copolymers of VDF are also important.

Since the high melt viscosity of PTFE resins prevents processing by conventional extrusion and molding techniques, they are processed by sintering techniques similar to those used in powder metallurgy. Although PTFE can be converted into practically any form (rods, billets, films, fibers, tubing, or coatings) by these techniques, the lack of melt processibility is frequently a handicap. Research on melt-processible forms of PTFE began almost immediately after its discovery [5]. The first to be developed was a TFE−HFP copolymer called FEP (fluorinated ethylene–propene) copolymer [6]. The FEP resins, commercialized in 1960, share nearly all the properties of PTFE, but are also processible by extrusion and injection molding. However, the melting point of FEP is ca. 60 – 70 °C lower than that of PTFE; its maximum use temperature is also lower. Further research on TFE copolymers led to the development of perfluoroalkoxy (PFA) resins, which are TFE−PPVE copolymers [7] that were introduced commercially in 1972. These have the same high-temperature properties as PTFE resins and an even lower melt viscosity than

FEP resins; they can be processed by extrusion and injection molding. In 1970 ETFE resins (TFE–ethylene copolymers) were commercialized [8]. They exhibit improved mechanical properties and far better processibility than other TFE copolymers. In addition, they can be cross-linked by high-energy radiation. The maximum use temperature, however, is lower than that of PFA or FEP.

Among the fluoroplastics that contain monomers other than TFE, PCTFE was the first to be commercialized. Extensive development work was carried out on this polymer during World War II in conjunction with the Manhattan Project [9]. Compared to TFE resins, PCTFE is harder, more resistant to creep, and less permeable. It has the lowest permeability to moisture of any plastic. Chlorotrifluoroethylene copolymerized with VDF provides an improved resin for film manufacture. However, ECTFE is the most important CTFE copolymer [10]. These resins are similar in properties and uses to ETFE copolymers.

Poly(vinyl fluoride) (PVF) contains the smallest amount of fluorine (41.3 %) of any commercial fluoropolymer, but possesses many of the properties of more highly fluorinated polymers [11]. It was commercialized in 1961 by Du Pont under the trade name Tedlar. It is used mainly in coatings for metal, plastic, paper, and similar substrates to provide resistance to weather, chemicals, staining, and abrasion.

Poly(vinylidene fluoride) (PVDF) shares many of the characteristics of other fluoropolymers such as thermal and oxidative stability, as well as outstanding weatherability [12]. However, the arrangement of alternate fluorine and hydrogen atoms leads to unusual polarity within the polymer chains, with a dramatic effect on dielectric properties and solubility. An unusual product made from PVDF is a film with piezoelectric properties. Copolymerization of VDF with a small amount (< 15 %) of HFP reduces stiffness and improves processibility for certain wire coating applications.

2.2. Polytetrafluoroethylene

Polytetrafluoroethylene [*9002-84-0*] (PTFE) is a straight-chain polymer of tetrafluoroethylene (TFE) of the general formula

$$-(CF_2CF_2)_n-$$

It has a high crystalline melting point (327 °C), very high melt viscosity (10–100 GPa · s at 380 °C), and a high maximum use temperature (> 260 °C). In addition, it exhibits unusual toughness down to very low temperatures (< −200 °C); its molecular mass is extremely high ($10^6 - 10^7$). It is insoluble in all known solvents and resists attack by most chemicals. Dielectric loss is low, whereas dielectric strength is high; antistick and antifriction properties are most unusual. Although these properties give PTFE great commercial value, they also rule out processing by conventional thermoplastic techniques.

Polytetrafluoroethylene is produced in three forms: *Granular PTFE* is prepared by suspension polymerization. The coarse product is cut to uniform particle size and processed by powder metallurgy techniques. *Fine powder resins* are prepared by dispersion polymerization and coagulation by high-speed agitation. The fine powder resins consisting of uniform particles of 0.2 µm diameter are mixed with a lubricant such as kerosene and processed by a cold extrusion method called paste extrusion. The third form of PTFE is an *aqueous dispersion.* The dispersion products are processed by latex processing techniques (dip coating or spray coating) followed by baking at high temperature which causes coalescence into a continuous film.

Manufacturers of PTFE resins include Ausimont (Algoflon and Halon), Daikin Kogyo (Polyflon), Du Pont (Teflon), Hoechst (Hostaflon), ICI (Fluon), and the former Soviet Union (Ftoroplast). The People's Republic of China also manufactures PTFE products.

2.2.1. Production

Polymerization. Tetrafluoroethylene must be polymerized with great care to avoid thermal decomposition of the monomer, which can disproportionate explosively to carbon and carbon tetrafluoride:

$$CF_2{=}CF_2 \longrightarrow C + CF_4 \quad \Delta H = -316.4\,\text{kJ/mol}$$

This reaction, which generates the same explosive force as gun powder, can be initiated by hot spots formed during polymerization. Because of the high heat of polymerization of TFE

and the excellent insulating qualities of the polymer, hot spots can develop if mixing is not adequate or polymerization is not controlled. Therefore, equipment and polymerization vessels must be adequately barricaded to prevent injury or death in the event of monomer decomposition. Polymerization in storage vessels can be prevented by the addition of inhibitors such as terpenes, mercaptans, or amines. However, these must be completely removed from the TFE before use.

Tetrafluoroethylene is polymerized in aqueous medium by two different processes. In the first, little or no dispersing agent is employed and vigorous agitation produces a coagulated granular resin. In the second procedure, a fluorinated surfactant is employed and agitation is very mild, producing small spherical particles dispersed in the aqueous medium. In the latter process, coagulation of the dispersion is avoided until after polymerization is completed. Subsequent precipitation of the particles produces fine powder resins which are converted to finished products by paste extrusion. The dispersion can also be concentrated and stabilized by addition of a nonionic surfactant. These stabilized aqueous dispersions can be applied by spray or dip coating.

Granular Resins. Granular resin was the first commercial PTFE product. The first granular resins were made from pure TFE with no other ingredients except initiator. Currently, however, some granular resins contain traces of certain comonomers such as PPVE [13], [14]. Sometimes granular polymerization is carried out in the presence of a small amount of a dispersing agent. Alkaline buffering agents are used occasionally. In the early stages of granular polymerization, a dispersion is formed, but the polymer soon coagulates. Subsequent polymerization occurs on the solid particles in a gas–solid reaction in which the water acts primarily as a heat-transfer medium. The polymerized product consists of stringy, irregularly shaped particles, which can exceed a millimeter in size. However, the specific surface area of these particles is over $2\,m^2/g$, which is ca. 1700 times the observed outer surface area. Therefore, the particles must be very porous and spongelike, as is confirmed in photomicrographs.

The "as-polymerized" products cannot be used as such, but must be cut to uniform particle size to provide sinterability. Coarse cut products have good powder flow, but leave a high void content after sintering. Finely cut resins give void-free moldings, but have reduced powder flow. A good compromise between ease of handling and ease of molding is achieved by reducing the particle size to 400 – 800 μm [15]. For some applications (ram extrusion of tubes and rods), the cut resins are partially presintered for better handling.

Fine Powder Resins. Fine powder resins are produced by polymerizing TFE in the presence of a dispersing agent such as ammonium perfluorooctanoate [16]. The process partially resembles emulsion polymerization. The polymer is highly crystalline and has little ability to solubilize the monomer. In addition, the polymer is insoluble in the monomer, as is typical of an emulsion polymerization. Many of the principles of emulsion polymerization apply to this process. Initially, only pure TFE polymers were prepared in this way, but products containing traces of comonomers such as HFP, CTFE, and PPVE are also made [17], [18]. The properties of these modified fine powders vary with the type and manner of addition of the comonomer.

The dispersion product must not coagulate during polymerization but must be sufficiently unstable to allow coagulation at the end of the polymerization cycle. Very gentle stirring prevents premature coagulation during polymerization. The average particle size is ca. 0.2 μm. The specific surface area is ca. $12\,m^2/g$, which agrees well with calculated values. Unlike the granular products, the dispersion particles display little, if any, porous structure. During the coagulation phase, the nonwettable polymer floats to the surface, where it is drawn off and dried.

Aqueous Dispersions. Aqueous dispersions are made by the same polymerization process used to prepare fine powder resins. The crude dispersions can be polymerized to give different average particle sizes. The most commonly used dispersion has an average particle size of ca. 0.2 μm. The "as-polymerized" dispersion must be stabilized and concentrated before use. A nonionic surfactant such as Triton X-100 is normally employed for stabilization. The dispersion

is concentrated thermally to 60 – 65 % solids. Other additives such as thiotropic agents and fillers may be used to modify the dispersion further.

Filled Resins. A variety of fillers are utilized by PTFE manufacturers and processors; they include glass fibers, graphite, asbestos, molybdenum sulfide, and bronze. Fillers can be blended dry with the PTFE powder before molding or can be coagulated with the dispersion to produce a filled fine powder. The filler serves to improve wear resistance, increase hardness, or reduce creep.

2.2.2. Properties

Physical Properties. The structure of PTFE chains is unusual in that they are completely linear. The branching that occurs during the free-radical polymerization of polyethylene cannot take place during the polymerization of TFE. Furthermore, PTFE chains are stiffer than polyethylene chains because their fluorine atoms are larger than hydrogen atoms. Steric hindrance prevents a PTFE chain from assuming a planar zigzag structure; instead, it is forced to adopt a zigzag structure with a helical twist along the chain axis. Crystals of PTFE are made up of chains with a 180° twist every 13 to 15 carbon atoms, depending on the temperature. The high melting point of PTFE (327 °C) is due to the small entropy change produced during melting, which in turn results from the stiffness of the chains [19].

The chemical bonding forces within the chains, between the chains, and the polymer surface are unusual:

The C–F bond energy is among the highest known. However, the interchain bonding forces are very weak, and the surface energy is very low. This combination of unusually strong and weak forces results in many unique properties.

The melting point of once-melted PTFE is 327 °C, but high molecular mass, virgin unmelted PTFE melts at a higher temperature (342 °C). Differential scanning calorimetry (DSC) indicates that the 342 °C melting point is irreversible and the subsequent melting point is 327 °C. Electron-microscopic studies of dispersion particles indicate that the rodlike crystals in virgin PTFE are fully extended with few defects [20]. Virgin PTFE particles are 92 – 98 % crystalline. The crystallinity of once-melted PTFE varies with molecular mass and the rate of cooling from the melt. However, commercial grades are usually 45 – 75 % crystalline.

Themolecular mass of PTFE cannot be determined by the usual methods that require dissolution of the polymer because there is no known solvent for PTFE below 300 °C. However, the number-average molecular mass has been estimated from the determination measurements of end groups. Because the molecular mass of PTFE is very high, the concentration of end groups is very low. A quantitative method must be sensitive to less than 1 ppm of end groups. An elegant method tags the end groups with radioactive sulfur in the initiator [21]; the sulfur from the initiator must be retained in the polymer with no loss by hydrolysis. When persulfate is used as the initiator, the resulting sulfate end groups are hydrolyzed to carboxylic acid end groups and no radioactive sulfur is detected in the polymer. However, when an iron–bisulfite initiator is used, the sulfur is retained in the polymer because the initiating species (a bisulfite radical, $HOSO_2\cdot$) gives rise to hydrolytically stable sulfonic acid end groups.

A series of polymers was prepared, using the radioactive bisulfite–iron initiator, with molecular masses in the range of industrial interest. The number-average molecular masses were calculated from the radioactive sulfur content, assuming two sulfonic acid groups per polymer chain. The calculated molecular mass ranged from $3 \cdot 89 \times 10^5$ to $8 \cdot 9 \times 10^6$. These samples were used to calibrate other methods for measuring the molecular mass of PTFE resins, such as the standard specific gravity (SSG) method [22]. Since the rate of crystallization varies inversely with molecular mass, samples of high molecular mass have a lower SSG than those

of low molecular mass; typical values for polymers of commercial interest range from 2.14 to 2.20. The SSG method is widely used with PTFE resins. The correlation between number-average molecular mass $\bar{M}_n$ and the SSG is given by the following relationship:

$$\mathrm{SSG} = 2.612 - 0.058 \log_{10} \bar{M}_n$$

Studies on the melting behavior of virgin PTFE by DSC [23] has led to another method for measuring molecular mass. The following relationship was found between number-average molecular mass and heat of crystallization (ΔH_c, J/g):

$$\bar{M}_n = 2.1 \times 10^{10} \cdot \Delta H_c{}^{-5.16}$$

In addition to its crystalline melting point at 327 °C, PTFE has several transition temperatures [19]. Two crystalline transitions, at 19 and 30 °C, have a significant effect on product behavior. Below 19 °C, the polymer crystallites exist in an almost perfect three-dimensional array. Above 19 °C, the triclinic unit cell changes to a hexagonal unit cell. Slight untwisting of the chains is observed in the cell from 13 CF_2 groups to 15 CF_2 groups per 180° twist. The transition at 30 °C is only ca. one-tenth as large as that at 19 °C. The hexagonal unit cell disappears above 30 °C, but the rodlike hexagonal packing of the chains in the lateral direction is retained. As measured by torsion pendulum, two important amorphous transitions occur at ca. −97 °C and +127 °C, these transition temperatures are dependent on frequency. The lower transition ranges from −110 to −73 °C when measured at frequencies from 0.033 to 90 Hz. The higher temperature transition ranges from 120 to 140 °C over the same frequency range.

Mechanical Properties. The mechanical properties of PTFE are affected by processing variables such as preform pressure, sintering temperature, and cooling rate, as well as by polymer variables such as molecular mass, particle size, and particle-size distribution. Properties affected are the flex life, tensile strength, elongation, permeability, stiffness, resilience, and impact strength. Properties such as the coefficient of friction, low-temperature flexibility, and thermal stability are relatively unaffected. Typical values for the mechanical properties of granular and fine powder PTFE resins are listed in Table 2. Further data are given in [24–26].

The crystalline transition at 19 °C causes a volume change of 1.0 – 1.8 % and must be taken into account when precision parts made from PTFE are designed.

The coefficient of friction of PTFE is unusually low. Static friction decreases with increasing load and is less than the dynamic friction which frees PTFE from stick – slip problems. Because of the low surface energy, only liquids with extremely low surface tension (e.g., perfluorocarbon acids) can wet a PTFE surface. Surfaces can be made wettable by treatment with alkali-metal compounds (e.g., sodium naphthenate) which, however, also increases the coefficient of friction.

The effect of fillers on the mechanical properties of PTFE is shown in Table 3; tensile strength, elongation, and the coefficient of friction are not significantly affected. In contrast, wear resistance is dramatically improved: the wear factor of the bronze-filled material is only 1/250th that of unfilled PTFE.

Electrical Properties. The very low dielectric constant of PTFE (2.1) does not change over a wide range of temperature (−40 to +250 °C) and frequency (5 Hz to 10 GHz). Such electrical behavior is attributed to PTFE's highly symmetrical structure composed solely of carbon–fluorine bonds, in which all electrical dipoles are exactly balanced. Similarly, the dissipation factor is extremely low and independent of temperature or frequency. Resistivity and dielectric strength, on the other hand, are very high, as is arc resistance; PTFE leaves no carbonized path. The electrical properties of PTFE are given in Table 4.

Electrical properties can be adversely affected by voids, which may reduce the dielectric strength and corona resistance of fabricated parts. Voids must be minimized to achieve optimum electrical insulation.

Chemical Resistance. Polytetrafluoroethylene is resistant to attack by most chemicals, including aqua regia, hot fuming nitric acid, hot caustic, gaseous chlorine, chlorosulfonic acid, organic esters, ketones, and alcohols. The only materials known to attack PTFE are molten alkali metals, chlorine trifluoride, and gaseous

fluorine at elevated temperature and pressure. Some highly fluorinated oils can swell or dissolve PTFE near its melting point. A list of chemicals that are compatible with PTFE is available [27].

Flame Resistance. Polytetrafluoroethylene is one of the most flame-resistant polymers known and does not support combustion in air. It has an extremely high limiting oxygen index (LOI) of 96 %, i.e., it burns only in almost pure (96 vol%) oxygen.

Weatherability. The weatherability of PTFE is remarkable; it is completely unaffected by all types of weather from dry desert heat to humid jungle conditions. Test films showed no change after 20 – 30 years of continuous exposure in Florida.

Radiation Resistance. On exposure to a high-energy electron beam or gamma radiation, PTFE undergoes degradation rather than cross-linkage. In the absence of oxygen, stable radicals are produced which slow down the rate of degradation. However, in the presence of air,

the radicals react with oxygen which accelerates scission and degradation. On exposure to 10^4 Gy (1 Mrad) of radiation in air, PTFE loses 50 % of its original tensile strength. Irradiation also affects its electrical properties: resistivity decreases, whereas the dielectric constant and dissipation factor increase.

Thermal Stability. In both air and nitrogen, PTFE has an extremely high thermal stability. Rates of decomposition are not measurable below ca. 440 °C, decomposition rates are high at 540 °C. In vacuum pyrolysis of thin films, first-order thermal decomposition occurs, the TFE monomer being the main product [28]; the activation energy is 347.4 kJ/mol. The melt viscosity decreases during pyrolysis which probably involves random chain cleavage followed by depolymerization (short kinetic chain length) and termination by disproportionation.

2.2.3. Processing

Granular Resins. Moldings are produced from granular resins in three steps: First, the dry powder is placed in a mold and compressed at moderate temperature to produce a preform that is strong enough for handling without breaking. The preform is than placed in an oven at 380 °C to allow the particles to coalesce. This operation is called sintering. The final step is controlled cooling to produce the desired crystallinity. Granular resins are available in a number of forms that are optimized for different types of molding. High-flow resins are used in small and automatic moldings. Finely divided resins are preferred for large billet moldings to which they impart superior properties. Presintered resins are easier to handle and are preferred in ram extrusion applications. Most PTFE manufacturers give detailed descriptions of molding equipment and procedures [29].

Automatically molded articles require no further finishing after molding. However, large billets and rods are subsequently skived or machined. Film and sheet are produced by skiving a billet on a lathe. Precision parts can be machined from ram-extruded rods. Another method, called coining, is used for articles that are too complicated to make by machining. In this operation, a sintered molding is heated to the melting point, quickly pressed into a mold cavity, and held under pressure until it resolidifies. Coined moldings are limited in their upper service temperature. After long periods at high temperature, they return to their original precoining shape.

Fine Powder Resins. The paste-extrusion process for fine powder resins represented an important advance in PTFE processing. It permits the manufacture of continuous PTFE tubing and continuous PTFE coatings on wires.

In paste extrusion, 15 – 25 wt % of lubricant (a petroleum fraction, usually kerosene) is mixed with the fine powder resin. The wetted powder is then gently shaped into a preform at low pressure. (Fine powder resins are extremely sensitive to shear; great care must be taken to avoid shearing the powder before extrusion, otherwise processibility may be lost.) The preform is forced through a die mounted in the extruder. The high shear exerted at the die fibrillates the powder and confers "green strength" to the extrudate. The lubricant is then evaporated and the extrudate is sintered at 380 °C to coalesce the elongated particles. Drying and sintering are performed consecutively by passing the extrudate through a multistage oven located directly after the extruder. Residence time in the oven can vary from a few seconds for thin-walled wire insulation to a few minutes for large-diameter tubing. Extrusion pressure depends on the reduction ratio, the extrusion rate, the lubricant content, and the extruder characteristics.

Paste extrusion is also used to produce unsintered tape. Lubricant mixing and extrusion are the same as above. The product is extruded into rods, which are calendered on hot rolls to the desired dimensions.

Different fine powder resins have been developed for different applications. Powders that are suitable for high reduction-ratio applications, such as wire coatings, are not usually suitable for medium reduction-ratio applications such as tubing. (The reduction ratio is the ratio of the die diameter to the product diameter.) Thread sealant tapes are generally produced with other special grades. New types of fine powder resins are constantly being developed, leading to both improved and new applications and processing techniques [30–32].

Dispersion Resins. In general, PTFE dispersions are concentrated to 50–60 % solids and stabilized by a nonionic surfactant. The dispersions are applied to various substrates by spraying, flow-coating, dipping, coagulating, or electrodepositing. Films can be made by casting the aqueous dispersion on a supporting surface, drying, baking, and cooling. If the film is too thick, cracks develop; the maximum film thickness per application is ca. 40 µm. Thicker coatings are made by casting and baking a series of layers.

An important application of PTFE dispersions is cloth impregnation. The woven cloth (e.g., fiber glass) is usually dipped into the dispersion and dried and sintered as in film formation. In some cases, the fiber is coated with the PTFE dispersion before weaving. Dispersions are also used in the production of PTFE fibers [33]. The dispersion is mixed with a matrix-forming medium such as viscose and spun into fibers through a spinneret and coagulating bath. The fibers are heated to remove the matrix polymer, sintered, and drawn for spinning.

2.2.4. Uses

About half of the PTFE resin that is produced is used for electrical purposes [34]. A major application is PTFE-insulated hookup wire used in military and aerospace electronic equipment. Polytetrafluoroethylene is also used in coaxial cables wrapped with PTFE tape, as insulation for airframe and computer wires, as well as in electrical components and "spaghetti" tubing.

Other important uses of PTFE resin are found in fluid-conveying systems, where it is used for gaskets, molded packings and seals, piston rings, bellows, overbraided hose, and lined pipe. Laboratory apparatus is also made of PTFE.

In static and dynamic load supports, large quantities of PTFE are used for bearings, ball- and roller-bearing components, and sliding bearing pads. The most commonly use known is as a release coating; PTFE-coated cookware utilizes a large amount of resin each year. Sheet and pressure-sensitive tape also serve for release applications.

Architectural fabrics are made by coating heavy-duty glass fabric with PTFE dispersions. These materials have outstanding weatherability and are resistant to chemicals, microorganisms, and fire. They have been used to enclose football stadiums and shopping centers.

Fibers and filaments are used in the production of PTFE filter cloth. Highly porous fabrics (e.g., Gore-Tex) are prepared by a process based on the fibrillation of high molecular mass PTFE. These fabrics have a high permeability for water vapor, but none for liquid water. They are widely used in outdoor wear and camping accessories.

A small but important use for PTFE is in medicine [35]; due to its inert and antiadhesive character, it is a highly suitable material for implants in the human body.

The main uses of the principal commercial PTFE resins are given in Table 5.

Table 5. Uses of PTFE resins

Type of resin	Uses
Granular	
Agglomerates	Gaskets, packing, seals, bearings, sheet, rod, heavy wall tubing, and tape
Coarse cut	Tape, molded shapes for chemical, mechanical, electrical, and nonstick applications
Fine cut	Molded sheets, tape, wire, wrapping, tubing, and gasketing
Presintered	Rods and tubes
Fine powder	
High reduction ratio *	Wire coating and thin-walled tubing
Medium reduction ratio *	Tubing, pipe, overbraided hose, and spaghetti tubing
Low reduction ratio *	Thread-sealant tape, pipe liners, tubing, and porous structures
Dispersion	
General purpose	Impregnation, coating, and packing
Coating	Film and coating

* Ratio of extrusion-die diameter to product diameter.

2.3. Tetrafluoroethylene–Hexafluoropropylene Copolymers

Copolymers of tetrafluoroethylene (TFE) and hexafluoropropene (HFP) are commonly referred to as fluorinated ethylene–propylene (FEP) resins [*25067–11-2*]. They are linear, perfluorinated copolymers:

The presence of HFP in the polymer chain reduces the tendency to crystallize. Thus, a copoly-

mer with a much lower molecular mass than the corresponding homopolymer TFE retains toughness adequate for most applications. The molecular mass of commercial FEP resins is only ca. 1/100th that of commercial PTFE resins. This results in a ca. 10^6-fold reduction in melt viscosity. Resins made of FEP have melt viscosities in the range of 1 – 10 kPa · s at 380 °C, which enables standard plastics processing techniques, such as extrusion and injection molding, to be used. In spite of their much lower molecular mass, the properties of FEP resins are largely comparable to those of PTFE resins. The FEP resins have outstanding chemical resistance, nonflammability, weatherability, and electrical, antiadhesive, and low-friction properties. The maximum use temperature of 200 °C, however, is 60 °C below that of PTFE resins.

Several grades of FEP molding powder have been developed for different requirements. The lowest viscosity is shown by FEP 110, which is designed for injection molding. The melt viscosity of FEP 100 is 2 – 3 times higher than that of the 110 grade. It is intended for general purposes, but is used mainly for extrusion. Another extrusion-grade resin, FEP 140, with a melt viscosity about twice that of FEP 100, provides significantly higher stress–crack resistance. The highest viscosity grade, FEP 160, is used in making linings for chemical process equipment and other applications requiring maximum stress–crack resistance. An aqueous dispersion of FEP, containing 55 wt% solids, is stabilized with a nonionic surfactant.

Du Pont produces FEP resins under the Teflon trade name. A similar product is manufactured by Daikin Kogyo of Japan and sold under the Neoflon trade name. The FEP resins are available in the form of extruded pellets (molding powders) and as an aqueous dispersion.

2.3.1. Production

Copolymerization can take place in aqueous or nonaqueous media. Because it is much less reactive than TFE, HFP is present in larger proportions in the mixture. In aqueous media, a dispersing agent such as ammonium perfluorooctanoate is normally employed. Persulfate is usually preferred as a free-radical initiator. Dispersion polymerization conditions are very similar to those employed for PTFE fine powder resins (see also page 6) [6], [36]. Agitation must be gentle to avoid premature coagulation. The control of FEP polymerization is difficult because HFP content and melt viscosity must be maintained within narrow limits to achieve the proper balance between polymer properties and processibility.

In aqueous polymerization, unstable acid end groups are formed, which must be removed during finishing. Otherwise, they decompose during fabrication, causing bubble formation and discoloration [37]. Polymers synthesized in a nonaqueous medium, with fluorinated peroxides or azo compounds as initiators, do not contain unstable end groups [38].

2.3.2. Properties

Physical Properties. The FEP resins are random copolymers of TFE and HFP. The HFP content is usually expressed as an HFP index (HFPI), which is the ratio of IR absorbances at ca. 980 and 2365 cm^{-1}. Commercial FEP resins have HFPIs between ca. 3 and 5.5 [6]. The actual HFP content of FEP resins can be determined by a high-temperature ^{19}F-NMR technique [39]; a typical FEP resin contains 8.5 mol% of HFP.

The crystallinity of "as-polymerized" FEP is lower than that of "as-polymerized" PTFE (70 % vs. 98 %). After processing, crystallinity depends on the molecular mass and the rate of cooling from the melt. The crystallinity of FEP moldings is usually ca. 50 %.

Like PTFE resins, FEP resins are insoluble in all known solvents. This precludes the determination of molecular mass below 300 °C by the usual methods. Number-average molecular masses have been estimated by measuring the concentration of acid end groups before finishing. (Polymerization in aqueous media, gives 0.05 to 0.20 mol% acid end groups.) The number-average molecular masses of commercial grades are between ca. 125 000 and 300 000 [40]. However, molecular mass is normally specified in terms of the melt-flow index, measured at 380 °C in a melt rheometer of the type used for polyethylene equipped with a corrosion-resistant barrel, piston, and die (ASTM D-2116). Melt-flow index values range from ca. 1.5 for the

highest viscosity grade (FEP 160) to ca. 20 for the lowest viscosity grade (FEP 110).

Typical FEP resins have a crystalline melting point from ca. 260 to 280 °C, depending on their HFP content, and do not exhibit any other crystalline transitions (the 19 °C transition in PTFE is absent in FEP). An amorphous transition is observed at 90 – 150 °C, depending on frequency of measurement. A second amorphous transition occurs below −150 °C [41].

The thermal stability of FEP resins is lower than that of PTFE resins, but is adequate for processing up to at least 380 °C. Thermal decomposition occurs in two distinct stages. In the first, HFP is preferentially split out of the backbone at a rate that is about 4 times faster than that found in normal PTFE decomposition. The second stage involves the decomposition of the remaining PTFE backbone, at the same rate as that of PTFE decomposition.

Mechanical Properties. The mechanical properties of FEP are very similar to those of PTFE resins. The absence of the 19 °C transition in FEP resins eliminates the volume change observed in PTFE resins at this temperature. The coefficient of friction is slightly higher in FEP resins than in PTFE. However, the static coefficient is lower than the dynamic coefficient, which avoids stick–slip. Typical values of mechanical properties are given in Table 6.

Table 6. Mechanical properties of FEP resins ∗

Property	Value	ASTM
Relative density	2.14 – 2.17	D 792
Tensile yield, MPa	12	D 638
Tensile strength, MPa	21	D 1708
Elongation, %	300	D 1708
Flexural modulus, MPa	660	D 790
Compressive strength, MPa	15	D 695
Hardness, Shore D	59	D 2240
Izod impact strength, J/m	no break	D 256
Coefficient of thermal expansion, K^{-1}	9.3×10^{-5}	D 696

∗ FEP 100

The temperature dependence of the tensile properties of FEP and PTFE resins is similar from ca. −250 to +200 °C. However, above 200 °C, the FEP properties deteriorate rapidly, whereas the PTFE properties remain satisfactory up to at least 260 °C. Thus, the maximum use temperature of FEP is 60 °C below that of PTFE resins.

As with PTFE, fillers can be added to FEP resins to increase wear resistance and stiffness and to lower creep. The maximum loading of fillers is controlled by processing considerations. Available compositions include 30 % bronze filled, 20 % graphite filled, and 10 % fiber glass filled. These all have high *PV* (pressure–velocity) values desirable for use as bearings.

The surfaces of FEP can be made wettable by corona discharge or by treatment with sodium naphthenate or with amines in a hot oxidizing atmosphere.

Electrical Properties. The electrical properties of FEP resins (Table 7) and PTFE resins (Table 4) are virtually identical. However, the effect of voids on the electrical properties that is observed in PTFE resins is absent in the void-free FEP resins. Because of the stability of FEP in dielectric measurements, the National Bureau of Standards has selected Teflon FEP resins as reference standards. The electrical properties of FEP are unaffected by prolonged exposure to water or a temperature of 200 °C. Only corona ignition affects the dielectric life of FEP. If the voltage stress is too low to cause corona discharge, dielectric life is infinitely long at any frequency.

Table 7. Electrical properties of FEP resins

Property	Value	ASTM
Dielectric constant		
100 kHz	2.03	D 1531
1 MHz	2.02	
Dissipation factor		
100 kHz	0.0003	D 1531
1 MHz	0.0008	
Surface resistivity, Ω/m^2	$> 10^{15}$	D 257
Volume resistivity, $\Omega \cdot cm$	$> 10^{17}$	D 257
Dielectric strength, 3.2-mm sheet, kV/mm	20.0	D 149
Arc resistance, s	no carbon track	D 495

Chemical Resistance. Like PTFE resins, FEP resins are inert to practically all chemicals and solvents, with the exception of fluorine at elevated temperature and pressure and molten alkali metals or sodium hydroxide. Adsorption of chemicals is usually less than 1 % even after long

exposure at an elevated temperature. Adsorption is completely reversible and has no effect on the polymer. Permeation of gas and vapor through FEP is slower than through most other plastics.

Radiation Resistance. The effect of gamma-ray or electron-beam irradiation on FEP and PTFE is largely degradative. In the absence of air, the radiation resistance of FEP is 10 times greater than that of PTFE. In the presence of air, however, both degrade at about the same rate. In the absence of air, irradiation at low dose rates at a temperature above the alpha transition (>150 °C) results in cross-linking [42]. However, this treatment is not of practical importance.

Weatherability. Both FEP and PTFE resins exhibit the same outstanding weatherability. After 15 years' exposure in Florida, the tensile properties and light transmission of a crystal clear FEP film remained unchanged.

Flame Resistance. The flame resistance of both FEP and PTFE is outstanding; FEP does not support combustion in air and has a limiting oxygen index (LOI) of 96 %.

2.3.3. Processing

Extrusion and Injection Molding. Conventional methods such as extrusion and injection molding are employed for processing FEP. However, FEP has a higher melt viscosity and lower critical shear rate than many other thermoplastic materials, which makes processing more difficult. Molten FEP can corrode the metals used in extruders and injection molding machines. Equipment parts that come into contact with molten FEP resin should be constructed from more corrosion-resistant materials (e.g., Hastelloy C or Inconel) [43].

Critical shear rates, above which melt fracture occurs, are low and range from $20\,s^{-1}$ for FEP 100 to $2\,s^{-1}$ for FEP 160. The resulting low production rates preclude the use of pressure-extrusion techniques. Fortunately, FEP resins have a high melt strength and can tolerate high draw-down ratios without fracture. Melt-draw techniques make high production rates possible. In addition, FEP can be extruded into wire coating, tubing, rods, and film of various sizes. It can be extruded over such materials as silicone rubber, poly(vinyl chloride), glass braid, metal-shielded cables, twisted conductors, and parallel multiconductor cables. Concentrates of any desired color can be blended with standard resins.

Injection molding is best carried out with the lowest melt viscosity grade (FEP 110 resin). Recommendations for molding equipment, designs, and operating conditions are available from the manufacturers. Bottles, flasks, beakers, and other laboratory ware are typical FEP products that can be made by injection molding.

Dispersion Coating. Aqueous FEP dispersions are processed in essentially the same way as PTFE dispersions. They are usually coated on the substrate (e.g., glass cloth) and the water is evaporated. The coating is then fused by heating above the melting point. Because of the lower melt viscosity of FEP, fusion is quicker than with PTFE resins. In addition, continuous films, free of pin holes, are more readily achieved. Sometimes FEP dispersions are used to provide a final coating on a PTFE coating.

2.3.4. Uses

Electrical applications comprise most of the uses of FEP resins, including hookup wire, interconnecting wire, coaxial cable, computer wire, thermocouple wire, and molded parts. Other applications include lined pipes and fittings, lined tanks, overbraided hose, heat exchangers, and laboratory ware. Mechanical uses include antistick applications such as conveyor belts and roll covers. Film is used in solar-collector windows because of its light weight, excellent weatherability, and high solar transmission.

2.4. Tetrafluoroethylene–Perfluoro-(Propyl Vinyl Ether) Copolymers

Copolymers of TFE with perfluoro(propyl vinyl ether) (PPVE) are called perfluoroalkoxy (PFA) resins [*26655-00-5*]. They have the following general formula:

These resins were developed after FEP resins and were designed to overcome the disadvantages of FEP resins in comparison with PTFE resins, i.e., lower thermal stability and poorer mechanical properties at high temperature. The ether group in the side chain of PFA resins eliminates steric strain at the branching point, which is responsible for the reduced thermal stability of FEP resins [44]. In addition, the large perfluoropropoxy side group in PFA reduces the crystallinity much more than the trifluoromethyl side group in FEP; it is ca. 6 – 8 times more effective on a molar basis. Thus, the comonomer content of PFA resins is substantially less than that of FEP resins even though the former are tougher. The melting point of PFA (305 – 310 °C) is only ca. 20 °C below that of PTFE. The thermal stability and maximum use temperature of PFA and PTFE resins are the same. The melt-flow rates and critical shear rates of PFA resins are higher than those of their FEP counterparts, which makes PFA resins easier to process. In addition, PFA resins have all the other advantages of PTFE resins: antistick performance, resistance to virtually all chemicals, low coefficient of friction, nonflammability, and excellent electrical properties.

Du Pont manufactures PFA resins under the Teflon PFA tradename. Similar resins are produced by Hoechst (Hostaflon TFA) and Daikin (Neoflon AP).

2.4.1. Production

Copolymerization. The copolymerization of TFE and PPVE can be carried out in aqueous [45] or nonaqueous media [46]. The aqueous process resembles the dispersion polymerization used for PTFE fine powders and FEP resins (see page 6). However, in contrast to the FEP process, in which HFP is the principal reaction ingredient, only a small amount of PPVE is present in the PFA reaction mixture. This is because (1) PPVE is ca. 10 times more reactive than HFP and (2) a much smaller amount of comonomer is incorporated into PFA compared to FEP. This can lead to inhomogeneity in the copolymers produced in the aqueous process. However, the addition of a small amount of fluorocarbon diluent to the aqueous polymerization mixture gives a uniform distribution of PPVE in the product. Another complication of this copolymerization process is the tendency of the growing PPVE radical to terminate by a rearrangement chain transfer:

This reaction competes with the usual chain termination by coupling, and can result in a polymer with a very broad molecular mass distribution. The use of chain-transfer agents such as methanol can keep the molecular mass and molecular mass distribution within desired limits [47].

Nonaqueous polymerization uses fluorinated peroxide initiators to produce stable end groups. Again, chain-transfer agents are required to keep the molecular mass and distribution within the desired limits. However, because of the PPVE radical rearrangement, some acid fluoride end groups are always present in the nonaqueous product. These groups can be stabilized by reaction with methanol or ammonia [48] or preferably with elemental fluorine [49].

Polymer finishing is simpler for PFA than for FEP resins. The aqueous dispersion product is coagulated, washed, dried, and heated to remove volatile components and unstable end groups. The resulting powder can be used directly for coating and the like or extruded into molding powders for standard extrusion and molding applications. The dispersion is also concentrated and stabilized for spray or dip-coating applications. Nonaqueous products are dried to remove solvent and extruded directly into molding powders. Several grades of PFA resins are available for extrusion and molding applications.

2.4.2. Properties

Physical Properties. Perfluoroalkoxy (PFA) resins undergo a single first-order transition at their melting point (305 – 310 °C). They do not display the other first-order transitions present in PTFE resins. Torsion-pendulum measurements revealed three second-order transi-

tions at −100, −30, and 90 °C. The crystallinity of "as-polymerized" dispersion polymer was 65 – 75 %. Samples slowly cooled from the melt had 58 % crystallinity.

The thermal stability of PFA resins is comparable to that of PTFE resins. Although they can be processed at temperatures up to 425 °C [50], degradation occurs on prolonged heating at or above 425 °C. Below its melting point, PFA does not decompose. Samples of PFA aged in an air oven at 285 °C for 2 years showed no deterioration; in fact, tensile strength, ultimate elongation, and flex life increased.

Mechanical Properties. The mechanical properties of PFA resins resemble those of PTFE and FEP resins at room temperature, but above 200 °C, PFA resins are superior to FEP resins. The high-temperature mechanical properties of PFA resins are equal or superior to those of PTFE resins. Both PFA and PTFE resins have a maximum use temperature of 260 °C. The low-temperature mechanical properties of the two resins are equivalent. The mechanical properties of PFA are shown in Table 8.

The wear and friction properties of PFA and FEP resins are similar. The static coefficient of friction is lower than the dynamic coefficient; consequently the polymer is free of stick–slip behavior. Fillers such as fiber glass or bronze powder improve the wear resistance of PFA, FEP, and PTFE resins.

Electrical Properties. The electrical properties of PFA, PTFE, and FEP resins are essentially the same [51]. The dielectric constant of PFA (2.06) is slightly higher than that of FEP (2.03).

Flame Resistance. Perfluoroalkoxy resins have the same nonflammability characteristics as PTFE resins. The limiting oxygen index (LOI) is over 95 %. According to Underwriters Laboratories (UL 94), PFA resins are self-extinguishing and classified 94 VE–O.

Radiation Resistance. High-energy irradiation affects PFA, FEP, and PTFE resins similarly. The PFA resins have about the same rate of degradation as PTFE resins in air, but resist radiation better under vacuum.

Chemical Resistance. Perfluoroalkoxy resins have outstanding resistance to chemicals and solvents, and are unaffected by strong oxidizing acids, bases, halogens, organic acids, aromatic and aliphatic hydrocarbons, alcohols, aldehydes, ketones, ethers, amines, esters, chlorinated compounds, and polymer solvents. Perfluoroalkoxy resins can be attacked by alkali metals and elemental fluorine at elevated temperature and pressure.

Optical Properties. Perfluoroalkoxy films have good optical properties; they are colorless and transparent in thin sections, and are translucent in thicker sections. Energy transmission is best in the IR region (87 – 93 %) followed by the visible (80 – 87 %) and UV regions (55 – 80 %).

2.4.3. Processing

Perfluoroalkoxy resins may be processed by conventional techniques, such as extrusion [52], injection molding [53], transfer molding, and rotocasting. Dispersions are available for spray and dip coating of fabrics and other substrates. High-temperature PFA melts can be corrosive to conventional stainless steels; more corrosion-resistant metals such as Hastelloy-C or Xaloy 306 are recommended for equipment parts that come into contact with the melts. Processing temperatures of ca. 330 – 425 °C are recommended. Residence times at the upper temperature limit should be kept short (< 10 min) to avoid polymer degradation.

Perfluoroalkoxy resins have higher melt-flow indexes than their FEP counterparts and consequently have higher critical shear rates before the onset of melt fracture (Table 9). Because of their higher inherent thermal stability, PFA resins can be processed at a higher temperature than their FEP counterparts. This results in a further increase in melt-flow index and critical shear rate for PFA resins. Thus, PFA resins can also be processed at significantly higher rates than their FEP counterparts.

Intricate articles that are difficult, if not impossible, to mold from FEP 110 resin, can be readily injection-molded from PFA 340 resin. The superior molding behavior of PFA is due to its favorable high-temperature mechanical properties, allowing the use of higher mold temper-

Table 8. Mechanical properties of PFA resins

Property	PFA 340	PFA 350	ASTM
Tensile yield, MPa			
23 °C	14	15	D 1708
250 °C	3.5	4.1	
Tensile strength, MPa			
23 °C	28	31	D 1708
250 °C	12	14	
Elongation, %			
23 °C	300	300	D 1708
250 °C	480	500	
Flexural modulus, MPa			
23 °C	655	690	D 790
250 °C	55	69	
Hardness, Shore D	60	60	D 2240
MIT∗ flex life, cycles	50 000	500 000	D 2176
Coefficient of thermal expansion, K^{-1}	6.7×10^{-5}	6.7×10^{-5}	D 696

Table 9. Melt-flow index and shear rate of FEP and PFA resins

Grade		Melt-flow index,	Critical shear rate,
FEP	PFA	g/10 min ∗	s^{-1}
100		6	20
	340	14	50
140		3	8
	310	6	16
160		1	2
	350	2	6

∗ The melt-flow index is the amount of resin extruded at 372 °C in 10 min (ASTM D2116).

atures (not far below the melting point of the resin). With FEP resins, mold temperatures must be below 200 °C because poor mechanical properties above 200 °C make ejection of the article from the mold without damage or distortion impossible.

Other molding procedures often used with PFA resins are transfer molding and rotocasting. Transfer molding is used for valve liners and similar products. Rotocasting is used for large structures such as drums and tanks. A special PFA powder, developed for rotocasting (TE-9749), gives a uniform, bubble-free casting. In this procedure, the heating cycle may range from 90 to 180 min at 355 – 365 °C. The thermal stability of PFA is more than adequate for this procedure.

Powders can be used to produce thin layers of PFA on various substrates. The surfaces to be coated are heated above the melting point of the PFA and the powder is sprayed on. The powder melts on the surface, which is then cooled.

A dispersion form (PFA 335) is available for coating metals, glass fabrics, and similar substrates. The dispersion can be processed by the techniques used with PTFE dispersions (see page 10).

2.4.4. Uses

Perfluoroalkoxy resins are used for producing high-quality electrical insulation and molded components. Other important uses are for bellows and expansion joints and liners for valves, pipes, pumps, and fittings. Tubing and film are also produced. Film can be oriented to give products with specialized properties. Equipment made from PFA is used extensively in the semiconductor industry for demanding chemical handling applications.

2.5. Tetrafluoroethylene–Ethylene Copolymers

Tetrafluoroethylene and ethylene have a strong tendency to alternate during polymerization. Thus, TFE–ethylene copolymers [*25038-71-5*] (ETFE resins) are composed mainly of alternating sequences of the two monomers and have the following structure:

$$-(CF_2CF_2CH_2CH_2\text{-})_n-$$

The alternating comonomer units are responsible for the unique properties of ETFE resins; they have a high tensile strength, moderate stiffness, high flex life, outstanding impact strength, good abrasion resistance, and very high "cut-through" resistance. Their electrical properties are similar to those of other TFE polymers. The ETFE resins have low dielectric constant, high dielectric strength, excellent resistivity, and a low dissipation factor; they also display good thermal stability and excellent chemical resistance. Unlike other TFE copolymers, ETFE resins have a high resistance to high-energy radiation. They are cross-linked by low doses of electron beam or gamma ray radiation. The cross-linked products have improved high-temperature properties, including resistance to cut-through by a hot soldering iron. The processibility of ETFE resins is superior to that of other TFE copolymers (the critical shear rate of ETFE resin is ca. 250 times higher than that of FEP resin). They are particularly well suited to extrusion and injection molding.

Unmodified TFE–ethylene copolymers have poor thermal stress–crack resistance, which severely limits their utility. This problem has been largely overcome by incorporating 0.1–10 mol% of termonomers, such as perfluoro(alkyl vinyl ethers) and perfluoroalkylethylenes, in the polymer backbone [54–56]. Commercial ETFE resins are all modified in this way. The thermal stress–crack resistance of modified ETFE resins is a function of the amount of termonomer and the melt viscosity of the resin. Processibility (extrusion rate), on the other hand, is mainly a function of the melt viscosity. Lowering the melt viscosity improves processibility, but reduces stress–crack resistance. Raising the melt viscosity improves stress–crack resistance, but reduces processibility. Several grades of commercially available modified ETFE resins provide different compromises between processibility and thermal stress–crack resistance to meet a variety of use and processing requirements.

Du Pont produces a series of modified ETFE resins under the Tefzel trade name. The 210 grade has the lowest viscosity and is designed for fast extrusion coating of small diameter wires that do not require maximum thermal stress–crack resistance. The 200 grade is a general-purpose resin designed for both extrusion and molding applications. The 280 grade has the highest viscosity and the best stress–crack resistance. It is designed for applications requiring maximum thermal stress–crack resistance. Other modified ETFE resins are produced by Asahi Glass (Aflon COP), Ausimont (Halon ET), Daikin (Neoflon EP), and Hoechst (Hostaflon ET).

2.5.1. Production
